Jorge et al. found that poststroke patients who received escitalopram showed more improvement in global cognitive functioning than did patients who received placebo or problem-solving therapy—indeed, of the antidepressant effect of the SSRI [61]. Similarly, in the Fluoxetine for Motor Recovery after Acute Ischemic Stroke (FLAME) trial, a randomized, double-blind, placebo-controlled study in patients with ischemic stroke and hemiplegia or hemiparesis, treatment with fluoxetine over 3 months was associated with improvement in motor recovery, independent of the antidepressant effect of fluoxetine [62].

**Electroconvulsive Therapy**

ECT is a safe and effective treatment that may be used in cases of severe or psychotic depression or when more conventional therapies cannot be used or are ineffective or intolerable to patients. Found to be particularly helpful for the depressive states accompanying stroke, Parkinson’s disease, and dementia, ECT has become part of the standard of care for treatment of severe depression in the medically ill [63]. ECT is also used to treat catatonia.

There are no absolute contraindications to ECT, but patients with unstable cerebro- or cardiovascular disease or increased intracranial pressure warrant closer scrutiny [64–66]. The decision to proceed with ECT, or not, is made after a careful weighing of the risks of the treatment itself on any underlying physical morbidity against the risks of ongoing untreated depressive illness. This calculation is best done by a psychiatrist experienced in ECT in consultation with an anesthesiologist and other specialists. The latest research in this area has examined the
memory impairment associated with ECT and the relationship of lead placement (e.g., bifrontal, bitemporal, and unilateral) to cognitive function [67–70].

Psychologic Management

Although pharmacologic treatments are the mainstay of treatment for depression in the ICU, psychologic remedies are also important. Patients often benefit from information, clarification, reassurance, and support. Psychologic therapies are most useful in cases of adjustment disorder with depressed mood, often as an adjunct to pharmacologic interventions. Brief psychotherapy at the bedside can facilitate increased resilience and hope.

When patients come to the ICU, they are often terrified about the outcome of the illness that brings them there. They frequently believe that the illness, no matter how well controlled in the ICU, will continue to be life-threatening after discharge. Some patients believe that their illness will necessitate a radical change in lifestyle. For example, many cardiac patients secretly believe that having had an MI means they will never be able to have sex again. One way to help patients with such concerns is to ask specific questions about how they believe their illness will affect daily life in the future. In this way, one will hear the patient’s specific fears and be able to educate the patient about the realistic effects of the illness. Another example is the patient who is physically weak after an MI and thinks he or she is a cardiac cripple. The patient does not understand that the physical debility is the result of muscle wasting from prolonged bed rest. Education often reassures patients.

Another way to help patients cope with depression in the ICU involves learning about a patient’s premorbid activities. Because patients in the ICU feel stripped of their identities and are demoralized, showing interest in who they are and what is important to them can remind them that they are respected and have lives outside the hospital. Families also can be helped to have realistic expectations. Strategies to help patients and families cope effectively in the ICU are discussed in Chapter 161.
CONCLUSION

Treatment of depression in ICUs is multifaceted, and many difficulties are involved in treating depression in this setting. Nevertheless, aggressive treatment of depression in the ICU can drastically improve a patient’s sense of well-being and transform a demoralized, hopeless patient into an active participant in treatment. In this chapter, we have outlined the recognition, differential diagnosis, and treatment of depression in ICUs. We strongly advocate that depression be treated as a serious illness; although a depressed mood is sometimes understandable, a depressive disorder is never appropriate.
REFERENCES

The assessment of the suicidal patient is a significant challenge for any intensive care team. Even when a psychiatrist is consulted to conduct an expert assessment of risk and to assist with the formulation of a treatment plan, the intensivist’s ability to evaluate, manage, and safeguard the patient’s safety is essential. The evaluation and management of a patient—whether contemplating suicide or recovering from a suicide attempt—require an understanding of risk factors, protective factors, the interplay among these various elements, and the relationship between the staff and the patient. In addition, the primary medical team should be aware of the necessity for ongoing psychiatric care during and after the stabilization of acute medical issues.

This chapter reviews the epidemiology of suicide, risk and protective factors, parasuicide, and intervention and management strategies for suicidal patients in the intensive care unit (ICU).

**Epidemiology of Suicide**

Suicide is the 10th leading cause of death in the United States (7th in men and 14th in women) [1]. In 2013, suicide was responsible for 41,149 deaths, with higher rates among whites, men, and individuals between the ages of 45 and 64 years, with rates in this latter group increasing steadily over the last decade [1,2]. Also in 2013, 494,169 people presented to an emergency department for treatment of self-harm, and 224,811 people were hospitalized due to self-inflicted injuries [1].
RISK AND PROTECTIVE FACTORS

Although appraisals of suicide risk are incapable of absolute predictions of suicidal behavior, careful history-taking, detailed examination, and astute clinical judgment allow a comprehensive understanding and evaluation of risk factors, protective factors, and the interplay among them (Table 160.1).

Recent real or perceived loss

The first set of factors is sociodemographic, including age, gender, race, marital status, and religion. In general, men are more likely to complete suicide, whereas women are more likely to make attempts [3,4]. White men are more likely to attempt suicide than nonwhites; among nonwhite populations, rates vary [1,3]. Suicide rates are higher for two distinct age distributions: late adolescence to young adulthood and older than age 70 years [4]; however, over the last several years, rates have been increasing among middle-aged individuals and slightly decreasing among the elderly. In general, the suicide rate is greatest among divorced and widowed people, followed by single individuals, and married people [4]. The combination of age, gender, and marital status also plays a role; young widowed men have a particularly high rate of suicide [4]. There is more recent evidence suggesting that sexual orientation and gender identity and expression are associated with suicide risk as those identifying with minority orientations appear to have a heightened risk [3–5].

Some evidence suggests that religious beliefs and the strength of one’s religious convictions protect against suicide; however, for some, religion may increase suicide risk. For example, an individual who believes he will be reunited with his lost loved ones when he himself dies may be comforted by the idea of dying. Thus, the various meanings religion can have in different people’s lives mandate careful exploration with the patient of the role of religion in death and suicide [4].

Psychiatric illness contributes significantly to the risk for suicide. Retrospective studies have identified one or more psychiatric disorders in individuals who have completed suicide or presented following a suicide
attempt \([3,4,6,7]\). In addition, conditions that frequently occur with psychiatric illnesses (e.g., substance use disorders) increase suicide risk. Research indicates that risk may be particularly high when a mood disorder co-occurs with a disorder that results in increased distress level (e.g., anxiety disorder) or a disorder that is characterized by diminished restraint (e.g., conduct disorder or antisocial personality disorder) \([3]\). The presence of a past history of suicide attempts, suicidal thinking, feelings of hopelessness, self-injurious behavior, impulsivity, assaultiveness, and trauma (physical or emotional) is an important component of risk assessment. Whether a patient is in active outpatient psychiatric treatment—and compliant with it—is also a critical component of risk assessment. Psychological factors—coping skills, tolerance of emotions, personality traits, insight, and judgment—figure prominently in the estimation of how a patient handles stress.

The presence of a physical illness contributes to the risk for suicide \([3,4,8]\). Suicide risk is greater for patients with neurologic disorders (e.g., Huntington’s disease, organic brain syndromes, multiple sclerosis, and spinal cord injuries), and suicide attempts are more common in patients with epilepsy and other chronic diseases \([3,4]\). In addition, head trauma is associated with an enhanced risk for suicide, particularly when behavioral or cognitive sequelae result. Executive function deficits due to delirium, dementia, or mental retardation also contribute to the risk for suicide \([4,8]\). Other illnesses of significance are listed in Table 160.1.

Psychosocial stressors—including states of family life, work life, relationships, and finances; legal difficulties; and losses—are important considerations when assessing risk. A family history of psychiatric disturbances, substance use, or completed suicide may indicate potential genetic vulnerabilities in the management of these stressors and response to interventions.

Protective factors include the presence of supports (e.g., family, friends, and faith), the ability to identify specific and important reasons for living, responsibility for young children or other family members, extraversion and optimism, effective coping and problem-solving skills, and the general absence of risk factors \([3,4]\).

Risk and protective factors must be understood on a case-by-case basis \([4,6]\). Despite the significance of each factor, the weight to attribute to each element must be individualized, because the interaction among these features defines each patient’s unique risk. For example, a 70-year-old unmarried white man with an incurable malignancy may be protected from suicide by his religion’s prohibition against it and by his three grandchildren’s frequent visits.
PARASUICIDE

Some physicians may differentiate “genuine” suicide attempts (in which the person’s aim was to kill himself) from parasuicide, a deliberately self-harming but nonlethal act. Often, parasuicide or a so-called suicide gesture is not a failed attempt to kill oneself per se, but could be either a maladaptive way to cope with emotions or an effort to elicit a specific reaction from someone else, whether an emotional response (e.g., feeling hurt or sorry) or a behavioral one (e.g., forestalling abandonment or providing nurturance). As such, a physician may be tempted to construe parasuicide as less worrisome than an authentic attempt to end one’s life. However, these individuals require equal attention and caution because parasuicide often recurs; when repeated often enough, such behavior may prove lethal, even if death is unintended. In addition, individuals can struggle to recognize in hindsight what their true intent or motive was, and there can be ambivalence as to the outcome of their suicide gesture. A history of parasuicide or suicide gestures may increase the subsequent risk for suicide, particularly as intent and lethality are not necessarily correlated and as increasing feelings of hopelessness and negative outcomes may influence intent [9,10]. For example, a man who commits parasuicide in an attempt to keep his wife from divorcing him may not recognize the potential lethality of his overdose, and he may later feel genuinely suicidal if his wife ends up leaving him.
TREATMENT OF THE SUICIDAL PATIENT

Nonpharmacologic Interventions

A patient’s verbalization of intent to harm himself/herself poses a unique challenge for the ICU physician. Although such utterances can be variously motivated and belie different intentions, any such statement should be taken seriously and viewed as the patient’s request for help and support. Suicidal statements may take the form of explicit declaration or implicit action (e.g., refusal to eat or to cooperate with care). The suicidal act can be impulsive or deliberate. Because accurate prediction of which statements will result in action is impossible, the ICU team must institute effective precautions whenever a patient avows suicide.

The ICU team should implement close monitoring, in the form of constant observation by a one-to-one sitter, video monitoring, or more frequent checks of the patient. Physical restraint of a patient at ongoing risk may be necessary when constant observation is not possible [8]. Staff should be aware of potential means by which patients may harm themselves. Any opportunity of jumping from windows or of hanging should be minimized, if not eliminated. All materials that a person may use to harm himself/herself (e.g., razors, scissors, needles, glass, medications, and eating utensils) must be removed and any personal belongings searched for these items. Staff should also be aware of items brought in by visitors. The team should review medications and consider decreasing or discontinuing medications that may heighten impulsivity or disinhibition. Estimations of safety should be made at least daily.

The primary team must also identify and address among themselves any negative feelings they have about the patient. Emotional reactions to dealing with psychological problems in the ICU can include helplessness, insecurity, fear, anxiety, guilt, and sympathy. People who repeatedly attempt suicide or whose motives have been deemed “manipulative” can engender frustration, anger, and exhaustion with demands for constant attention, thereby creating distance between the patient and the treatment team. It is important to understand these feelings and to prevent them from hampering patient care and clouding recognition of a potentially unsafe patient. For example, patients with borderline personality disorder can “split” the staff (i.e., behave well for one subset of the staff and badly for another) [11]. Regular communication among staff members and between the staff and the patient can minimize splitting and prevent team members from feeling defensive or apologetic in the face of a critical and demanding patient.

An empathic approach that seeks to understand what the patient feels
can prevent these emotions from instigating counter-therapeutic responses. Even if a “suicide attempt” is an effort to elicit a particular response from others (rather than a genuine attempt to end one’s life), the desperation required to put one’s life at risk is nonetheless sobering. For people whose intent was to die, waking up from an unsuccessful suicide attempt can be accompanied by despair, shame, guilt, fear, anger, a sense of inferiority, or ambivalence about having survived. The physical discomfort of the life-sustaining measures employed in the ICU can compound such patients’ pain.

Medications

The question of whether and when to restart psychiatric medications following a suicide attempt can be a difficult one, particularly if the person attempted to kill himself/herself by an overdose of these agents. The decision to resume outpatient medicines must be guided first and foremost by accurate psychiatric diagnosis. They should not be restarted reflexively just because they had been prescribed previously; they should be ordered only if the patient has a bona fide psychiatric condition. Psychiatric consultation can be beneficial when the diagnosis is uncertain.

The next consideration is the patient’s physical condition and the medications’ effects on organs that the suicidal act may have compromised. Medications that are potentially toxic to impaired organs should not be restarted. Attention should also be paid to the patient’s level of arousal and the risks for seizures and arrhythmias because psychiatric medications may enhance these risks.

Anxiety is a potent risk factor for suicide and should be treated to prevent recurrence of suicidal behavior and intensification of suicidal thinking. Benzodiazepines can be particularly helpful in quelling anxiety, whereas neuroleptic medications—both conventional and atypical—are preferred when anxiety escalates into outright fear.

Psychiatric Consultation

Psychiatric consultation is strongly recommended whenever a patient’s safety from self-harm is uncertain. The consultant will address psychiatric diagnoses, suicide risk, medications, and disposition. Consultation can also be helpful in understanding the psychological dynamics between patient and staff. The patient who may be thinking about, or at risk of, self-harm but has not articulated a specific thought
also may benefit from expert consultation; elderly patients often do not report suicidal thoughts to caretakers [12].

When requesting a consultation, it is helpful to provide the consultant with as many details of the suicide attempt as possible (e.g., method, number of pills in cases of ingestion, and likelihood of rescue). The exact words used by a patient who makes a suicidal comment, as well as the context in which the statement was made, are critically important and should be included in the consultation request. Basic elements of the patient’s mental status (e.g., level of wakefulness, affect, the presence of psychosis, and ongoing suicidal thinking) should be determined and relayed to the psychiatrist. Clear documentation from the nursing staff and physicians will help the consultant follow the patient’s course and identify points of intervention.

Disposition

When medically and surgically stable, patients face two options for discharge—home or psychiatric facility. Patients who may benefit from or require continued treatment in a psychiatric facility are those whose risk factors outweigh their protective factors. This decision is usually made with the psychiatric consultant, who will also assist with placement, prior authorization (which is required by some insurance plans), and the handling of any legal matters (e.g., if the patient is unwilling to be hospitalized psychiatrically, and thus requires involuntary commitment).
CONCLUSION

Attempted suicide is a tragic consequence of mental and physical illness that represents a relatively small number of ICU admissions. Nonetheless, the care of a patient who is suicidal or has just attempted suicide requires attention to a number of details not usually considered in the management of a typical ICU patient. The ICU team must be cognizant of their emotional reactions to the patient and of patient–staff dynamics, vigilant for potentially dangerous objects in the physical environment, and knowledgeable about specific interventions, including constant observation of the potentially self-harming patient. Psychiatric consultation can be helpful in managing important aspects of care for this patient population, from diagnosis and safety assessment to medication management and disposition.

Chapter 161

Problematic Behaviors of Patients, Family, and Staff in the Intensive Care Unit
CRAIGAN T. USHER

Nobody realizes that some people expend tremendous energy merely to be normal.

*Albert Camus* [1]

The intensive care unit (ICU) is a stressful environment for patients, family, and staff [2–8]. Under extreme medical and psychologic stress, *everyone* in the ICU—patients and physicians alike—may fail to work together.

In exploring difficult patient–staff interactions, though we may use terms like “the hateful patient” [7], the “angry attending,” or the “problematic family member,” such language erroneously locates problems as arising solely from one individual and risks eschewing dimensional thinking (the notion that most people borrow from a spectrum of problematic-to-healthful coping strategies and defense mechanisms) in favor of overly simplistic categorical distinction (a patient is healthy or not, hateful or loving). As such, although critical care team burnout and the conditions that contribute to systemic stress—staffing constraints, health care system financial structures—are extremely important, this chapter focuses largely on patient behavior and how best to meet the needs of individuals whose behavior may be perplexing or vexing. The chapter outlines a basic approach to problematic patient conduct in the ICU; details common patterns of exasperating behavior of critically ill patients and practical ways of meeting the individual’s needs; and reviews operationalized modes of communication with families of patients in the ICU.
CRITICALLY ILL PATIENTS CAN BEHAVE IN WAYS THAT JEOPARDIZE ICU ACTIVITY. SOME PATIENTS BECOME CHILD-LIKE, CRYING OR WHIMPERING, TURNING AWAY FROM CARE PROVIDERS, REFUSING EXAMINATIONS. A NUMBER OF PATIENTS GROW DEMANDING OF NURSES’ AND PHYSICIANS’ ATTENTION; THEY HURL INSULTS WHEN PROVIDERS ARE NOT AS ATTENTIVE AS THEY WOULD LIKE. OTHERS MAY BE VIOLENT IN WORD OR ACTION, THREATENING STAFF AND EVEN PUNCHING AND KICKING CARETAKERS.

BEFORE DECIDING HOW TO APPROACH A DISRUPTIVE PATIENT OR FAMILY MEMBER, ONE MUST FIRST ANSWER THE QUESTION “DO I FEEL SAFE?” AND THEN “IS THE PATIENT SAFE?” ICU PERSONNEL ARE OFTEN TAUGHT TO OVERRIDE THEIR FEARS AS THEY PERFORM PROCEDURES THAT DEMAND BRISK, DECISIVE ACTION. UNFORTUNATELY, SUCH DENIAL MAY LEAD PHYSICIANS AND NURSES TO FAIL TO HEED THEIR INTERNAL SENSE OF ALARM AND DANGER REGARDING PATIENT BEHAVIOR, RESULTING IN INJURY TO PATIENTS AND STAFF. PARTICULARLY WHEN NEGOTIATING VERY POWERFUL EMOTIONS AND HOLDING LIFE-AND-DEATH DISCUSSIONS WITH FAMILY MEMBERS AND THOSE CLOSE TO PATIENTS, SOME PEOPLE MAY BECOME EXTREMELY EMOTIONALLY DYSREGULATED.

THOUGH MANY PATIENTS CAN BECOME DELIRIOUS AND COMBATIVE AND FAMILY MEMBERS DISCOURAGED AND DYSREGULATED IN CRITICAL CARE SETTINGS, FEW GROW VIOLENT OR USE FIREARMS [8,9]. STILL, GIVEN THE OVERALL GROWING PROBLEM OF GUN VIOLENCE IN THE USA, A BRIEF REVIEW OF HOSPITAL-BASED SHOOTINGS IS TIMELY. ACCORDING TO A STUDY BY KELEN AND COLLEAGUES [10], THERE WERE 154 HOSPITAL-RELATED SHOOTINGS AT 148 AMERICAN HOSPITALS BETWEEN 2000 AND 2011. MOST SHOOTERS WERE MEN (91%) AND THE MOST FREQUENT AREAS WHERE SHOOTINGS OCCURRED INCLUDED EMERGENCY DEPARTMENTS (29%), PARKING LOTS (23%), AND PATIENT ROOMS (19%). INCIDENTS TYPICALLY INVOLVED A SHOOTER TARGETING A PARTICULAR INDIVIDUAL, WITH MOTIVES INCLUDING GRUDGES (27%), SUICIDE (21%), “EUTHANIZING” AN ILL RELATIVE (14%), AND PRISONER ESCAPE (11%). A VERY LOW PERCENTAGE OF THESE INCIDENTS INVOLVED THE TARGETING OF NURSES (5%) OR PHYSICIANS (3%).

ALTHOUGH HOSPITAL STAFF CANNOT READILY INFLUENCE THE WIDESPREAD AVAILABILITY OF FIREARMS, THE RELATIVELY LAX GUN LAWS IN THE USA COMPARED TO OTHER NATIONS WITH FAR LOWER RATES OF GUN VIOLENCE [11], AND THE INADEQUACY OF MENTAL HEALTH SERVICES, THERE ARE THINGS THAT MEDICAL PERSONNEL CAN DO. FIRST, THOUGH HOSPITAL SHOOTINGS ARE VERY RARE EVENTS, STAFF SHOULD BE ENCOURAGED TO ERR ON THE SIDE OF CAUTION—SUMMONING SECURITY OR POLICE IF THEY FEAR THAT THERE IS AN IMMINENT THREAT OF CONFRONTATION OR VIOLENCE FROM FAMILY MEMBERS, FRIENDS/VISITORS, OR PATIENTS THEMSELVES. IT IS NOT A VIOLATION OF THE HEALTH INSURANCE
Portability and Accountability Act privacy rule to disclose information about a patient to law enforcement when a patient is considered to present a serious threat. In addition, sufficient security cameras, strategic placement of panic buttons, and making certain employees are well trained in emergency procedures not only for traditional “code” situations but also for instances of gun violence are crucial interventions. “Tuning into” a sense of alarm may involve administering calming medications, summoning security personnel if there is a risk of flight, and/or applying physical restraints in extreme situations.

“Tuning into” a sense of alarm may involve administering calming medications, summoning security personnel if there is a risk of flight, and/or applying physical restraints in extreme situations. Once the safety of the patient, other patients, and staff is assured, examination of the underlying causes of a patient’s taxing behavior follows. Because irritability and emotional lability are the final common pathway of myriad medical and psychiatric conditions and of normal emotional responses, precise determination of the etiology of a patient’s disruptive behavior is often vexing. Asking and answering the questions listed in Table 161.1 can be helpful in narrowing the vast differential diagnosis.

### Table 161.1 Key Questions about Behavioral Problems in the ICU

#### Safety
- Is the patient’s behavior dangerous? If so, how can I keep the patient and others safe?

#### Delirium
- Is the patient delirious? If so, am I effectively treating the underlying causes of delirium?

#### Psychiatric illness
- Does the patient have an anxiety, mood, or psychotic disorder or another psychiatric illness? If so, am I providing adequate treatment for these conditions?

#### Intoxication and withdrawal
- Is the patient intoxicated with or withdrawing from alcohol or another substance? Am I addressing the untoward effects of withdrawal?

#### Psychosocial stressors
- Can I reduce pain, sleeplessness, isolation, and other stressors related to being in the ICU?

#### Personality problems
What is the patient’s predominant mode of coping?  
How can I best manage this patient’s uniquely taxing coping strategies?

Delirium is a common source of troublesome patient behavior in the ICU. Patients who are hallucinating or harboring persecutory delusions that ICU staff are torturing them can be immensely problematic. Owing to its potentially lethal nature [15,16], delirium should be ruled out first as the driving force behind a patient’s disruptiveness. A full discussion of delirium is provided in Chapter 157.

After delirium has been excluded, it is important to look for major psychiatric illnesses, which are frequently exacerbated by the chaos, vulnerability, and prolonged inner tension associated with being treated in the ICU [17]. The intensivist should discern if the patient has a history of psychotic disorder (e.g., schizophrenia), affective illness (e.g., bipolar or major depressive disorder), or anxiety disorder (e.g., posttraumatic stress or panic disorder), and should—if no contraindications such as drug–drug interactions exist—order any medications that have been effective in treating these conditions in the past. As part of this psychiatric workup, a substance use history also is imperative; data from collateral sources (e.g., family, friends, and therapists) may be necessary to confirm the patient’s report. At any step in the process of assessing the roots of patients’ problematic behaviors, psychiatric consultation may be useful in establishing and confirming diagnoses and in guiding treatment.

While gathering data about psychiatric conditions and substance use, common sources of patient stress in the ICU—pain, sleeplessness, and isolation—should, as much as possible, be eliminated. Biancofiore and colleagues [18] showed that liver transplant recipients and patients who underwent major abdominal surgery identified “being unable to sleep, being in pain, having tubes in nose/mouth, missing husband/wife, and seeing family and friends only a few minutes a day as the major stressors.” Provision of adequate analgesia, effective sleep aids, and uninterrupted interaction with individuals closest to a patient often significantly curtails problematic behaviors.
COMMON PATTERNS OF PROBLEMATIC BEHAVIOR

Critical illness leads many patients to feel lonely, dependent, or anxious about the prospect of death; as well, traumatic memories may be re-awakened. To keep these unpleasurable feelings and recollections at bay, ICU patients deploy a broad array of psychologic defenses.

Some patients’ patterns of psychologic defense—that is, their personalities—are quite adaptive. By distracting themselves with television; enjoying the company of a loved one at their bedside; or engaging their caretakers with humor, forthrightness, and intellectualization, such patients contribute to ICU cohesion. On the other hand, some people lack the positive emotional backgrounds, reliable social supports, and ample psychologic armamentarium required to deal well with adversity. Such individuals may be said to have poor psychologic resiliency.

Patients with poor psychologic resiliency fall into two categories: (1) those with personality disorders who probably had difficulty navigating life even before becoming critically ill; and (2) those who have simply regressed and utilize primitive coping mechanisms that, outside the ICU, would be less apparent. Because the focus in the ICU is on the here-and-now, distinguishing between these two categories is unnecessary. More important is recognition of the four pathologic personality styles that frequently engender loathing in ICU personnel and require limit-setting and validation (Table 161.2).

| Narcissistic | Hypersensitive to loss of control and stature and defended against looking weak | • Denies severity of illness  
• Shows bravado  
• Critical of ICU staff and care  
• Validate patient’s plight and offer to help within reason  
• Acknowledge patient’s stature  
• Enlist patient as active partner in care and decision-making |
| Obsessive  | Hyperaware of loss of control and defended against looking weak               | • Excessive focus on medical facts and minutiae  
• Restricted affect; not apt to “show emotional cards”  
• Schedule patient and family meetings  
• Have a set amount of information to share with patient and family  
• Provide factual, opposed to nuanced, explanations of data  
• Avoid emotional commentary or inquiry |
| Dramatic  | Difficulty feeling cared for or thought of except within emotionally extreme exchanges | • Engaging and charming to some staff, denigrating and caustic to others  
• May have multiple allergies and phobias  
• May “fire” some staff and take exceptions to rules  
• Acknowledge patient’s positive attributes  
• Validate patient’s plight and offer to help within reason  
• Set limits as a team |
Dependency

Dependent patients demand assistance in nearly every aspect of their ICU experience. Through urgent requests for spoon-feeding, bedpan assistance, pillow adjustment, analgesia, and better food, among sundry other entreaties, dependent patients drive nurses and house officers to distraction. Yet, when examined through an empathic lens, dependent patients are incredibly fearful and leverage demands for care to keep their nurses and doctors in sight, thus reducing their anxiety. In this way, demanding patients are like the toddler who, unable to hold onto the mental image of his mother, wails when she leaves the room. These patients are hypersensitive to being alone. To mitigate these fears, nurses and doctors should make extra efforts to inform them of the care plan, how to call for urgencies, when they plan to return, when rounds will take place, and when family will visit.

Still, for many dependent patients, basic information of this sort is insufficient to quiet their incessant demands for anxiety reduction. In these situations, validation of these patients’ feelings, communication that their requests are understood, and explanation that the staff is unable to provide everything these patients want are key. These tasks are accomplished through “I wish” statements. For example, a particularly dependent and anxious patient in a busy ICU pled: “Doctor, I need you to check on me every hour, I am so scared!” The resident physician responded, “Your illness is very severe and frightening and while I wish I could visit you every hour, I have many people in the hospital to take care of, so I cannot be here quite so often. I promise, though, that I will visit you before I go home this evening at 5 o’clock and I will introduce you to the doctor who will be taking over.” His fear and desire for attention validated, secure in the knowledge his physician would return, this patient became far less anxious and demanding.

Narcissism

Being critically ill in the ICU leads even the most psychologically healthy to feel infantilized; hence, for most patients, regaining a sense of control is extremely important [22]. For some patients, however, this need to
regain control takes the form of demands and scathing critique. These patients often admonish nurses (“You’re not doing that the right way!”); belittle their doctors (e.g., calling young house staff “Doogie Howser”); and name-drop (“Dr. Smith is an expert cardiologist I play golf with, and he would never allow that”).

With such patients, it is best to appeal to, rather than to confront, their narcissism. When the narcissistic patient looks around the ICU, all he sees are his inadequacy, inability, and incapacity. The intravenous pump reminds him he cannot feed himself; the ventilator brings to mind that he cannot breathe unaided; the bedside commode or bedpan is a glaring reminder of his inability to move about nimbly. By using words that remind the patient that, despite his infirmities, he is still a valuable person, one can “join” the patient and incurs less wrath and invective. Such “joining” can be done by respectfully calling patients “Mr.,” “Ms.,” and “Dr.,” as appropriate. It is also helpful to ask them about their lives outside the hospital, promoting the notion that they are not frail and infantile but able-bodied adults endowed with personal agency but presently suffering critical illness.

The patient with substantial narcissistic needs appreciates any control he can be afforded. Even if this means only controlling the light switch, choosing the hour the physical therapist will arrive, or using patient-controlled analgesia, the narcissistic patient revels in feeling like a partner in his care. Finally, avoidance of power struggles and sharing of dilemmas are key to working with these patients effectively. For example, an astute medical intern said to a “very important person” (VIP) in the ICU: “While I realize the catheter may be uncomfortable, if I were to remove it right now, it is likely I would have to replace it tomorrow. I can do this if you’d like—it is your decision—but I am concerned that this would cause you even greater pain.” Knowing he had a choice, the VIP felt greater self-agency and was thus able to defer to the doctor’s educated opinion, electing to leave the catheter in for the time being.

**Obsessionality**

The obsessive patient is rules-based and acts much like a school-aged child clinging to the rules of a board game. Following the obsessive mantra “a place for everything and everything in its place,” the obsessive patient wants to know what his X ray shows before it is taken. His day can rise and fall on laboratory minutiae. Like the narcissistic patient, the obsessive individual may feel his control slipping away at times of illness. However, rather than acting in a haughty manner to deny that illness is stripping him of his control, the obsessive patient attempts to attain mastery over his condition through excessive focus on detail. A master of “losing the forest for the trees,” the obsessive patient gets lost in the fine
points. He asks questions incessantly and wants to manage his own treatment. For example, one obsessive patient with myasthenia gravis saw an “L” next to her hematocrit and demanded to know why she wasn’t being transfused when her hematocrit was 32.3%. When her nurse sat down at her bedside and provided a synopsis of her lab work and the team’s rationale for management, the patient was soothed. For all patients, but particularly for obsessive ones, it is helpful to: (1) have in mind a set amount of information that the team wants to share with the patient, thus allowing the patient the mastery over illness he craves but without overwhelming him; (2) announce a regular time nurses and physicians will share a progress report; and (3) use scientific/deductive reasoning to explain each step in treatment.

**Dramatic Behavior**

Patients who are extremely dramatic may project their own thoughts and discomforts onto others or believe their own perceptions and ideas to be entirely accurate. For example, if they are feeling lonely, vulnerable, or inadequately validated, such patients may accuse staff of purposely ignoring them, belittling them, or being incompetent. Meanwhile, they may also project warm feelings and suddenly become overly intimate or familiar with some staff members. Dramatic individuals—many of whom meet criteria for borderline or histrionic personality disorder in the official psychiatric parlance [20]—engage their physicians and nurses in relationships that are intensely intimate or staggeringly conflictual. The dramatic patient thus seduces some staff members while alienating others; with some personnel, the dramatic patient acts charming and delightful, whereas with others the dramatic individual is devaluing, belligerent, and toxic. When clinicians who have had completely different experiences with a dramatic patient confer, they are at odds over how to handle the patient’s demands. This discord creates tremendous tension, one that is relieved when clinicians acknowledge they have had contradictory emotional experiences with a patient. Once this “split” is named, the team can then strategize how best to set limits (Table 161.3).

---

**TABLE 161.3 Principles of Establishing Limits and Negotiating Conflicts in the ICU**

- Acknowledge the patient’s real struggles.
- Explain limits in a clear and concise manner. Avoid
jargon such as, “You are demonstrating unsafe behavior, sir. This is a non-smoking environment,” and simply offer, “You can’t smoke while you’re in the unit.”

- Before speaking with the patient, know what areas, if any, are flexible and make concessions to the patient in those areas.
- Determine consequences for transgressing limits in advance.
- Avoid long, drawn-out arguments, because they are rarely, if ever, useful. Leaving the patient’s bedside in order to cool down, think of a new strategy, or consult a colleague is better than acting impulsively.

Another feature of dramatic patients is their need to convey how much physical pain they are in (e.g., “Doctor, you don’t understand the pain I’m going through. I can’t possibly do physical therapy”). As with the dependent patient, communicating understanding of the patient’s plight—in other words, validating their feelings—is important. Statements such as, “Given all that you’ve been through, I can only imagine how hard this is” can be helpful. Further, even more than what is said, listening and eliciting the patient’s experience is usually most beneficial: “I want to make sure I better understand what you are going through. If you are willing to share, I would be grateful.”

When people talk, listen completely. Don’t be thinking what you’re going to say.

*Ernest Hemingway* [23]
COMMUNICATION WITH FAMILIES

Almost always for better, but occasionally for worse, family members are not mere visitors to the ICU [24]. Family members play an integral role in encouraging and comforting critically ill patients and informing distant loved ones of patients’ progress or problems. With the exception of those patients who, prior to hospitalization, expressed their preferences for medical care, relatives are also responsible for learning about a patient’s diagnosis and prognosis and making decisions for critically ill patients who lack the capacity to make medical choices for themselves.

It can be difficult to function in these roles, because the experience of having a family member in the ICU takes a psychologic toll. Family members of ICU patients suffer depression and anxiety; up to one-third of family members suffer posttraumatic stress symptoms 3 months after their family members are discharged from the ICU [5].

Adequate communication between ICU staff and family members of ICU patients is central to reducing family stress and dissatisfaction [25,26]; decreasing conflict around end-of-life decisions; limiting futile interventions [27]; and curtailing strife between families and ICU staff [28]. Some general principles of communication with families in the ICU include: providing clear and concise medical information; scheduling and keeping appointment times to meet with families; respecting the uniqueness of the family and the patient, listening for things that are special about both; and providing early diagnostic and prognostic information [29], even if this means saying, “I’m not sure” (Table 161.4).

**TABLE 161.4 CORE Principles of Communication with Families in the ICU**

Early Diagnosis and Prognosis

Even if it means saying, “I’m not sure,” try to inform the family early in the ICU stay.

Even with good communication, problems arise. Occasionally, before the physician can provide information regarding prognosis, family members will foreclose discussion and disagree with the doctor or other family members about how much workup or end-of-life treatment to pursue. Some special situations related to the emotional life of family members bear examination in further detail. These include: the guilty family member; the family member compelled to preserve the dignity or “fighter status” of their loved one; and the vindictive family member.

Physician interventions or “conversational reframes” in these situations are aimed, not at coercion, but at enhancement of doctor–family and family–family conversation about how best to proceed with a critically ill family member’s care.

Occasionally, the sibling, parent, or child of an ICU patient—who has played little role in the ailing family member’s life—attempts to rectify this estrangement by coming to the rescue at the eleventh hour. To assuage their guilt, these family members demand that “everything” be done for their relative, to the point of pushing for futile assessments and treatments. Reframing the dilemma for these family members, giving them a sense of authority, and explaining how they can be helpful can change the family–staff dialogue. For example, one intensivist told a particularly guilty son whose mother had suffered a severe stroke: “I know you’ve had to be away for several years and not been able to play a day-to-day role in your mother’s care. However, this is a really big opportunity to help support your mother, who is dying, and your sister, who is struggling. You can help your sister come to a well thought-out decision about your mother’s care.” By educating this young person about how he might help in the here-and-now, while also indirectly addressing his guilt, the physician altered this family member’s attitude.

When dealing with end-of-life care, some family members will demand that “everything” be done because they don’t want their loved one to appear weak. “But he’s a fighter,” some relatives protest. In these situations, one should listen closely to why it is important that the patient’s status as a “fighter” be maintained. Once this information is obtained, the ICU staff member can illustrate how the patient remains a “fighter” even when heroic measures are scaled back.

Some family members may be angry with the patient. Wasserman studied responses provided by relatives of patients who had attempted suicide and found that a family’s request for “do not resuscitate” orders sometimes reflected anger toward the patient [30]. Eliciting these feelings during a family meeting may help family members acknowledge
the hostile origins of their decisions and feel they have acted less impulsively and more thoughtfully about how to proceed with a loved one’s care.

Communication between ICU staff and a patient’s family may be disrupted when a family member does not want to make decisions on behalf of a loved one [31] or suffers symptoms of anxiety, depression, or another psychiatric illness. Such family members may derive great benefit from consultation with the ICU’s social worker or an outpatient psychiatrist. Finally, in those situations where discussions over care reach a standstill and interventions stimulate little movement, referral to an ethics consultant or committee (particularly with regard to end-of-life care) or patient-rights advocate (regarding a family member’s grievance) may be helpful in resolving conflict.

When an intensive care team faces the challenge of sharing with family members and patients “bad news” and having end-of-life care discussions, utilizing the SPIKES framework [32,33] for communicating with families may be particularly useful (Table 161.5). Utilizing this framework, practitioners pay special attention to Setting up the interview; eliciting patient’s and family’s Perceptions about their illness and treatment; Inviting patients and family members to be active participants in the process asking them about the quality (type) and quantity of information they would like; providing the patient and their supports with medical Knowledge; Empathically responding to the Emotions of those hearing bad news; and Summarizing and Sharing a Strategy for how best to proceed. Ultimately, no matter what protocol one utilizes, clinicians should remember that: (1) having a mindful framework versus “therapeutic winging it” is key; (2) there is great medical and psychologic intensity in this type of work and, as such, any kind of news (be it good or bad) is hard to deliver [34]; (3) even under the best circumstances, the most compassionate caregivers can sometimes come across as less empathic [35]; (4) problematic interactions can be an opportunity for self- and team reflection and improvement; and (5) learning to address the needs of families better requires an openness to reflection and whole-team commitment [36].

**TABLE 161.5 Empathically Sharing “Bad News” and Collaborating with Families: The “SPIKES” Protocol**
### Setting
- Set up the communication space for privacy
- Have the right people there (people important to the patient and to his/her care)
- Have tissues ready
- Anticipate what questions might be asked/information might be desired and have this ready
- Set aside sufficient time to have a thorough discussion
- If an interpreter is needed for optimal communication, have that individual ready

### Perceiving
- Listen and assess: “What questions do you have?” “What is your understanding of ____’s condition?” “What is your understanding of why we performed this test?”

### Inviting
- Appreciate that some patients and families may want technical information, whereas others want a summary
- Ask questions like: “What is most important for us to cover?” “How much detail would you like me to go into regarding what we’ve learned or about the proposed treatment?”

### Providing Knowledge
- Introduce ideas with sensitivity, beginning with phrases like: “I am sorry to say that …”
- Pause and ask for questions and ask for an invitation from the patient/family to continue
- Use lay language, avoiding jargon. Avoid the insensitivity of bluntness.

### Being Emotionally-attuned and Empathic
- Observe patients’/families’ emotions
- Consider that emotion and name it to oneself
- Identify the reason for this emotion (it may be coming as a surprise or confirm a worst fear)
- Connect the patient’s affect and what you believe is driving it (e.g., “I had also hoped for a better result.”)
- Assess that you have been accurately attuned

**Summarizing and Outlining Strategy**

- Summarize what has been discussed and reiterate the management strategy

CONCLUSIONS

Physicians, nurses, and other members of the critical care team are often confronted with patients and families whom they find unnerving, taxing, or even dangerous. Addressing difficult interactions and challenging personalities entails a commitment on the part of the practitioner to take an empathic stance, recognizing that behind the most troubling behavior is a person, someone in anguish whose words and actions represent his/her best attempts to cope with pain.

ICU staff should work to establish and maintain their and patients’ safety; exclude causes of disruptive behavior that can be amenable to medical intervention; and examine patients’ and family members’ predominant mechanisms of defense (as well as their own). Patients and family members with traumatic pasts, poor coping strategies, and/or formal personality disorders often respond to limit-setting and validation of their distress, entailing a description of how they are expected to act and what they can expect from their caregivers. Family members and loved ones play a crucial role in critical care; ensuring that they are collaborative members of the ICU team involves providing clear and early diagnostic information; conveying respect for the uniqueness of patients and their families; and providing regular, scheduled updates and clear, systematic team meetings regarding major decisions.

Recognition and Management of Staff Stress in the Intensive Care Unit

GUY MAYTAL

The intensive care unit (ICU) is a structurally, functionally, and socially complex entity with its own culture, personnel, protocols, and challenges [1]. Today, such units are frequently filled to capacity with complicated patients suffering from multiple life-threatening illnesses. As technology has advanced, patients with once terminal illnesses are surviving episodes of deterioration, raising ever more complicated ethical issues [2].

This environment can affect ICU staff adversely. The psychologic pressures on ICU personnel are myriad: increasingly sophisticated technologic advances; overwhelming amounts of data; burdensome demands on caretakers; long hours; nursing shortages; and trying ethical issues. Staff may not be prepared to handle their emotional reactions to these challenges while simultaneously tending to the technical and clinical aspects of intensive care.

This chapter reviews the general concepts of stress and burnout; the tensions associated with training and working as a physician or a nurse in an intensive care setting; and strategies for managing staff stress in the ICU.

STRESS

The physiologic, cognitive, and affective facets of stress are based on the seminal work of Selye [3] on the general adaptation syndrome. Selye defined stress as the nonspecific result of any demand on the body, and observed that different organisms and biologic systems respond to stress in a stereotyped and predictable three-part pattern. The initial alarm
reaction (characterized by activation of the sympathetic nervous system and various hormonal, immunologic, and psychologic responses) is followed by the stage of resistance, during which the organism establishes a temporary homeostasis by marshalling various reserves to adapt to the new situation. However, the body’s ability to adapt is finite, and, with continued exposure to the stressor, its reserves become depleted and the organism enters a stage of exhaustion.

Researchers in biology and sociology have expanded this work to encompass processes ranging from individual cellular responses to stress to the reactions of individuals and social systems to external and internal stressors. Over the past 50 years, the study of occupational stress (i.e., stress due to one’s work situation) has consistently demonstrated the significant adverse impact of excessive occupational stress on physical health, mental health, and decision-making. Regardless of the field, low job satisfaction is often predicted by a small number of factors: little participation in decision-making, ambiguity about job security, poor use of skills, and lack of clarity about role. These stressors are consistent with the demand–control model of the effects of job demands on worker’ well-being. This model predicts that the fewer demands and more control a worker has on the job, the less stress he will experience [4]. For example, the Return to Work Study found that subjects with low-demand, high-control jobs were substantially more likely to return to work after a period of medical disability [5].

Of the other well-recognized occupational stressors (including noise-related stress, nonstandard work hours, and excessive fatigue) [4], work overload and a poor social environment at work are the most significant determinants of work-related health problems. In particular, work overload and overall low job satisfaction are strongly associated with the development of psychiatric (particularly affective) problems. A meta-analysis of job satisfaction and health outcomes examined 485 studies (267,995 individuals) and concluded that poor job satisfaction was strongly associated with the development of depressive and other affective illnesses [6].

In addition to physical and mental health, decision-making also can be adversely affected by high levels of stress [7]. Awareness of one’s limited knowledge and problem-solving capacities, fear that bad outcomes will occur regardless of which choice is made, worry about making a fool of oneself, and fear of loss of self-esteem if the decision is wrong can force decision-makers to come to “premature closure.” Premature closure is a type of cognitive error in which the physician fails to consider reasonable
alternatives after an initial diagnosis is made. It is a common cause of misdiagnosis. Such premature closure can lead to incorrect or even harmful decisions [8,9].

In a work environment, including the ICU, stressors (both work-related and non–work-related, both internal and external) affect each individual in a unique manner as mediated by a variety of factors. The interaction between stressors and mediating factors can lead the individual to experience either strain or job satisfaction [10]. When this interaction leads to strain that is chronic or particularly intense (or both), burnout can occur.
BURNOUT SYNDROME

Coined by the clinical psychologist Herbert Freudenberger [11] in 1974, burnout syndrome has been viewed as a behavioral or a psychologic condition, as well as a process or a syndrome [12]. Research during the past three decades (especially by Maslach and colleagues) has narrowed the current definition to encompass the spheres of emotional exhaustion, depersonalization (i.e., negative or cynical attitudes regarding work), and the absence of personal accomplishment—particularly among individuals who do “people work” (Table 162.1) [13]. Although emotional exhaustion is the key component of the syndrome, people with all three symptoms experience the greatest degree of burnout [14]. Ultimately, this definition describes a process whereby highly motivated and committed individuals lose their spirit; their motivation for creativity; and, in the ICU, their belief in their ability to help people [15,16].

</table>

Many have argued that the cause of burnout lies in our need to believe that our lives are meaningful and that what we do is useful and important.
[15]. Work takes on a central role in providing some people with this sense of meaning in their lives. In a supportive environment, highly motivated individuals reach their goals and achieve success, which leads to a sense of meaningfulness that itself increases the original motivation. However, in an unsupportive environment, these individuals cannot accomplish what they set out to do and consequently fail. For people who expect a sense of meaningfulness from work, such failure often leads to burnout.

Everyone experiences stress, but only those who start their careers with high levels of idealism, motivation, and commitment are at risk for burning out: “You cannot burn out unless you were ‘on fire’ initially” [15]. Burnout occurs almost exclusively among individuals who work with people, arising from the emotional stress that such interactions engender. ICU staff tend to be idealistic, committed, and driven—the very attributes that render them susceptible to burnout.

For the individual, burnout is characterized by physical, emotional, and attitudinal symptoms. Physical symptoms are nonspecific and include chronic fatigue, headaches, insomnia, weight changes, and worsening of chronic medical conditions. Burnout can lead to increased consumption of tobacco, alcohol, and illicit drugs. Emotional symptoms include despair, hopelessness, and depression. Relationships can become disrupted and the ability to work can be compromised [13].

On an organizational level, cynical attitudes toward work, colleagues, and patients can isolate coworkers and precipitate staff conflicts. At some hospitals, job dissatisfaction and burnout have led to absenteeism, accelerated staff turnover, and severe staff shortages, which may limit the number of ICU beds available for patient admissions [17].
STRESS AND BURNOUT IN HEALTH CARE PROFESSIONALS

Stress is a common aspect of medical practice for physicians, nurses, and trainees. Not surprisingly, studies have reported a high prevalence of burnout in health care professionals. Rates of burnout among physicians range from 25% to 60%, depending on working conditions and medical specialty [18–20]; burnout can develop at any stage of a physician’s career. Shanafelt and colleagues surveyed 27,000 physicians and received 7,200 responses. They found that 45.8% of respondents had at least one symptom of burnout. In addition, physicians were more likely (than the general population) to have symptoms of burnout (37.9% vs. 27.8%) and to be dissatisfied with work–life balance (40.2% vs. 23.2%) [21]. Nurses also experience high levels of burnout. Studies of nurses indicate rates of 35% to 50%, depending on working conditions, clinical setting, and level of autonomy [14]. Multiple factors have been associated with burnout of health care professionals, but the best characterized include: heavy workload; stressful work environments (e.g., ICUs); severity of patients’ illnesses; and conflicts with coworkers or patients [22,23].

Physicians who experience burnout suffer physical (e.g., anorexia, insomnia, tachycardia, and hypertension) and psychologic (e.g., irritability, frustration, apathy, indecision, and depression) symptoms. Burnout leads to increased nurse distress, decreased patient satisfaction, increased mortality in the ICU, and substance abuse [24,25].

Along with its professional impact, burnout also has a significant personal impact on physicians and medical trainees. Oreskovich and colleagues surveyed 7,288 American physicians regarding their substance use behavior and associated risk factors. They found that 12.9% of male respondents and 21.4% of female respondents met criteria for alcohol abuse or dependence [26]. They also found that burnout was independently associated with alcohol use or dependence. Other associated factors included depression, suicidal ideation, lower quality of life, and lower career satisfaction. Similarly, a national study of 4,402 US medical students found that burnout was independently associated with an increased risk of alcohol abuse or dependence [27].

Just as concerning are the effects of burnout on the personal lives of physicians. Physicians’ personal relationships with spouses and children are damaged by burnout: “Being a physician is one of the few socially acceptable reasons for abandoning a family” [28]. Even more alarming is that burnout may be a contributing factor to increased suicidal ideation among physicians and physician trainees. A prospective study found that
burnout at baseline was an independent predictor of suicidal ideation over the following year, whereas recovery from burnout has been shown to decrease the frequency of suicidal ideation [29]. Burnout clearly has a significant impact on the medical profession and on the public it serves.
Competitive, highly driven, and able to delay short-term gratification indefinitely, people attracted to medicine are more likely to have personalities that render them susceptible to the detrimental effects of stress and to burnout. As a rule, they are success-driven, tend to be “people-pleasers,” and are unable to recognize their own limitations. Similarly, they do not often understand or attend to their own emotional and psychologic health and, citing the need to be “strong,” squelch their emotional reactions to stressful events [30,31].

Medical practice has changed dramatically over the past several decades, and many physicians who entered medicine to enhance their sense of control and mastery find themselves in a medical system that is increasingly out of their control [31]. Physicians have experienced a decline in status and autonomy alongside mounting work pressures. Under closer scrutiny by regulatory agencies and insurance companies, physicians have had to contend with ever growing amounts of paperwork. Owing to increased pressure to discharge patients, the acuity of patients in hospital settings has increased, “turnover” is more rapid, and interventions are more aggressive.

House officers, in particular, face a unique constellation of stressors. According to a review of burnout during residency training, the stressors faced by house officers are varied and include: burnout that is already present during medical school; intense time demands; lack of control over time management or planning; inherently difficult job situations; and strained interpersonal relationships [32]. All of these contribute to the risk of burnout in house officers.

In recent years, more quantitative evaluations of burnout have been undertaken at both the medical-student and resident level. A significant proportion of medical school graduates enter residency with high rates of burnout. One study of 1,428 fourth-year medical students found an overall prevalence of burnout of up to 49% [33]. Once in residency, this prevalence continues at about the same level or even increases to 60% [34]. Another study found the overall burnout rate in residency to range from 27% to 75% depending on specialty [35].

In an important longitudinal study that examined the impact of job stress on house officers, Tyssen and colleagues [36] followed 371 medical students from their last semester through the end of their internship. They found that 11% of these interns had mental health problems. The most important predictive factor was perceived job stress. Moreover,
perceiving oneself as deficient in clinical skills or knowledge at the end of medical school was related to a mental health problem during internship. Importantly, gender, lack of sleep, and number of hours worked weekly were not linked to mental health problems.

More recently, Shapiro and colleagues [37] studied the relationship between loneliness and social connectedness in an urban academic medical center internal medicine residency program. They found a high rate of burnout among the residents (47%) and a dose-dependent correlation between how lonely a resident felt and the degree of burnout.

More worrisome, burnout has been clearly demonstrated to affect residents’ clinical performance. Several studies have shown that patients cared for by residents with burnout are at increased risk of receiving suboptimal care and experiencing a medical error [38]. Burnout also impedes acquisition and assimilation of new knowledge, an essential purpose of residency. A study of nearly all US internal medicine residents found that those with burnout scored significantly lower on a national standardized examination of medical knowledge [39]. The differences in medical knowledge across the continuum of burnout were as large as the differences observed across an entire year of residency training.

Stress and burnout are associated not only with work hours but with a variety of internal and external factors; quality of teamwork, personality characteristics, and trouble with the work/home interface all contribute to the development of stress and burnout in house officers. A 12-year longitudinal study of medical school graduates found that specific personality traits (e.g., high neuroticism, low extraversion, and low conscientiousness) measured while in medical school strongly predicted the development of stress, burnout, and job satisfaction as a staff physician [40].

Despite work-hour restrictions, residents and fellows continue to shoulder stressful workloads that have a significant impact on their physiology and psychology. Gopal and coworkers [41] studied a single cohort of residents before (2003) and after (2004) restrictions on work hours were implemented. Residents in 2004 had less burnout, emotional exhaustion, sleep deprivation, and depression. However, the residents did not perceive any significant changes in their quality of life, and their learner satisfaction was significantly reduced.
STRESS AND BURNOUT AMONG INTENSIVISTS

Staff physicians—in particular those who work in ICUs—have a high prevalence of burnout syndrome. The protracted stress of working as a physician can lead to lower-quality patient care, disruptions in personal relationships, and even impairment of physical health [42]. Intensivists labor in an atmosphere of perpetual stress and often limited rewards. In addition, society often has unrealistic expectations of the physician not only as a professional but also as a spouse, parent, employer, and community member. Failure to live up to any of these can lead to a sense of failure [42].

Studies have attempted to quantify the way in which these stressors affect physicians who work in intensive care settings. Coomber and coworkers [42] surveyed all members of the Intensive Care Society in the UK (85% response rate, 758 respondents) to identify “distressed” doctors and to relate this state to “repeated and long-term exposure to job stressors.” They found that nearly 30% of the physicians surveyed were distressed, 12% were depressed, and 3% had suicidal thoughts. These physicians reported that the most stressful aspects of their work were the feeling of being overstretched, the effect of work hours and stress on personal/family life, and the pressure to compromise standards when resources were limited.

In a survey of 978 French intensivists, Embriaco and colleagues [22] found that 46.5% had a high level of burnout syndrome. Risk factors included female sex, increased workload, and conflicts with coworkers. Workload (as measured by number of shifts per month and length of time from the last day off) was associated with higher rates of burnout. Similarly, in a survey of 6,000 American physicians, female physicians were 60% more likely to report burnout than their male counterparts [43]. Conflicts with coworkers are associated with higher levels of burnout, whereas good relationships with nurses are a protective factor [22,43].

More recently, van Mol and colleagues completed a systematic review of the literature on burnout among health care professionals in intensive care settings. Reviewing 40 studies (including a total of 14,770 respondents), they found the prevalence of burnout among ICU
physicians to range from 14% (following a preventive intervention) to as high as 70.1% [44]. The authors concluded that working in an ICU correlates with a substantial risk of emotional distress.
STRESS AND BURNOUT AMONG INTENSIVE CARE UNIT NURSES

Although nurses and physicians work in the same physical environment, nurses have unique working conditions; emphasize different aspects of clinical care; and experience different stresses. Nurses usually work in the ICU indefinitely, compared to residents, and even critical care fellows and attendings, who rotate through different units in the hospital. Despite their relative permanence in the ICU, nurses do not generally accrue as much autonomy and stature as do physicians, which may lead to stress over career and organizational structure [45,46].

An important stressor that is frequently overlooked in the ICU is workplace violence. The ICU is often a setting of great emotional intensity for patients and their families. This can sometimes manifest as violent behavior. The ICU is also a setting where patients are delirious and agitated and can lash out physically against staff. Nursing staff in particular is vulnerable to physical violence by patients and families, with between 25% and 80% of acute-care nurses having reported patient violence in one form or another [47,48]. The short- or long-term exposure to any type of violence can result in negative consequences for nurses and adversely affect organizational climate. For nurses, there may be both physical consequences (e.g., injuries, temporary or permanent disability) and psychologic consequences (e.g., anger, fear, anxiety, posttraumatic stress disorder, reduced job satisfaction) [49,50].

There are also negative outcomes of workplace violence at the organizational level, including high staff turnover; decreased morale; nurse absenteeism; more frequent medical errors; more workplace injury claims; and increased costs due to disability leaves [51]. In Canada, 33% of workplace violence incidents occur in health-care and social-service settings, compared to 14% in accommodation or food services and 11% in educational services [52].

Multiple studies have found that nurses who work in critical care settings are at high risk of burnout (up to 30% to 40% of nurses surveyed) and higher risk of burnout compared to nurses in other settings [46,53]. Factors commonly found to be associated with burnout among critical care nurses include moral distress, emotional exhaustion, poor physical well-being, and limited autonomy regarding end-of-life situations [54].
MANAGEMENT OF STAFF STRESS AND BURNOUT IN THE INTENSIVE CARE UNIT

Given the deleterious effects of stress and burnout on ICU staff and patients, it is important to reduce and manage their impact. Various interventions for addressing this fall into several categories: enhancing a healthful lifestyle as a buffer against burnout; formal resilience training for ICU staff; and group-based interventions for managing stress and burnout. All have been shown to have efficacy in small trials or in descriptive papers; in addition, there is a growing number of studies demonstrating their statistical and clinical significance.

Lifestyle interventions aim to reduce staff stress and include relaxation training, time management, assertiveness training, team building, and meditation [13]. Strategies for coping, as proposed in the Bulletin of the American College of Surgeons, include maintaining healthful personal relationships and spiritual practices, seeking health care when needed, maintaining appropriate nutrition and physical fitness, and establishing work–life balance [55]. Having a peer network, supportive mentors, and institutional support are necessary for the success of these interventions.

Resilience refers to the ability of individuals to absorb life’s challenges and to carry on and persevere in the face of adversity; it is an internal resource for mitigating the negative effects of stress and maintaining mental health [56,57]. In recent years, different resilience training programs have been developed and studied. A recent meta-analysis found that resilience training programs have a small to moderate effect on improving resilience and other mental health outcomes [58]. Several small studies indicate that resilience training for physicians and nurses can ameliorate or prevent the onset of burnout [59–61].

Groups and workshops have been reported as useful in managing stress [62]. Gunasingam and colleagues described a study where medical residents were randomized to four debriefing sessions over 2 months or no debriefing sessions [63]. Residents in the debriefing sessions found them to be a source of emotional and social support. McCue and Sachs [64] described the effectiveness of a stress management workshop for medical and pediatric residents; it cost little, was positively received, and demonstrated significant short-term improvement in stress and burnout scores.

On the organizational level, adequate staffing, shared decision-making, active review of unit policies and procedures, freeing up time for patient care or research, bolstering administrative support, and allowing flexibility to curtail work/home conflict may help reduce stress and
increase job satisfaction [65].
CONCLUSION

Recognizing and attending to staff stress in the ICU are necessary to ensure the continued effectiveness and well-being of each individual and of the unit as a whole. Left unaddressed, staff stress and burnout can exact a heavy price. As Civetta [66] wrote:

We must accentuate the positive qualities of human capabilities that are beyond technological advancement.... A smile, a touch, confidence and security are still beyond our programming capabilities.... We must focus on our distinct human qualities of insight and caring. In this way, the popular view that intensive care is a depersonalizing environment can be replaced by the recognition that human beings are caring for human beings.

Acute Respiratory Failure due to Acute Respiratory Distress Syndrome and Pulmonary Edema

GILMAN B. ALLEN • POLLY E. PARSONS

INTRODUCTION

Acute Respiratory Distress Syndrome (ARDS) is defined by noncardiogenic pulmonary edema and hypoxemia in the setting of direct or indirect lung injury. ARDS represents a common pathologic endpoint of various potential insults to the lung that almost invariably lead to hypoxemic respiratory failure, requiring support with mechanical ventilation. Despite the confirmed success of protective mechanical ventilation strategies for lowering mortality [1,2] and ongoing efforts to discover other effective interventions [3–8], treatment of this condition remains largely supportive, and ARDS continues to be a major source of morbidity and mortality in the intensive care unit (ICU) [9,10]. Fortunately, an enormous body of research already exists on the pathogenesis of this condition, and advances continue to develop with regard to our understanding of ARDS, its prognostic implications, and how to best manage the condition medically.
ARDS was originally described in 1967 by Ashbaugh and Petty and defined somewhat arbitrarily, until an American and European Consensus Conference (AECC) definition was agreed upon in 1994 [11]. This definition was generally used clinically and epidemiologically, but it was limited by interpretations of timing for the onset of injury, poor interrater reliability of chest radiograph interpretations, and the influence of positive end-expiratory pressure (PEEP) on the P:F ratio [12,13]. To address these issues, the Berlin definition was established in 2012 [14]. ARDS is now defined as a diminished arterial oxygen pressure (PaO$_2$) to fractional inspired oxygen (FiO$_2$) ratio (P to F [P:F] ratio of less than 300), bilateral airspace disease on chest radiograph, and pulmonary edema from increased permeability, the latter defined by evidence of normal cardiac function [14]. The term “Acute Lung Injury (ALI)” has now fallen out of the definition in favor of a continuum of mild, moderate, and severe ARDS, in part to avoid the confusion that would frequently accompany the broad use of the term “ALI” when referring to generalized types of lung injury. Accordingly, in the Berlin definition, ARDS is now divided into three categories of severity based on the level of hypoxemia: mild (P:F ratio 300 to 201), moderate (P:F ratio 200 to 101), and severe (P:F ratio < or = to 100) [14]. However, because the P:F ratio can be effected by arbitrary ventilator settings [15], the new definition qualifies that the severity classifying P:F ratio be measured with PEEP of > or = to 5 cm H$_2$O. Several studies prior to the new Berlin definition had suggested that indices of oxygenation were not strongly predictive of outcome [16–18], but the cohort of patients used for this new definition demonstrated a link between increasing severity (by category) and both an increased risk of mortality and increased duration of mechanical ventilation among survivors [14].

Although the source of hypoxemia in ARDS is multifactorial, oxygenation is one of the most easily gauged markers of “lung injury” in the ICU and thus an important component of the definition. A more inclusive P:F ratio of less than 300 mm Hg can serve to identify patients earlier in their course, thus expediting the delivery of critical lifesaving interventions before progression to moderate or severe ARDS. For ARDS, the pulmonary edema is the result of capillary leak, a parameter that is difficult to measure in the clinical setting. Accordingly, non-cardiogenic pulmonary edema is defined using clinical parameters, which include the presence of “bilateral infiltrates” consistent with pulmonary edema on chest radiograph and either a pulmonary artery wedge pressure (PAWP) less than 18 mm Hg (when measured) or no clinical evidence of left atrial
hypertension [14]. However, because the group recognized that ARDS does not always exist exclusively without heart failure, the consensus more explicitly defines ARDS as “a syndrome of inflammation and increased permeability that is associated with a constellation of clinical, radiologic, and physiologic abnormalities that cannot be explained by, but may coexist with, left atrial or pulmonary capillary hypertension”[11].

Despite the great lengths taken to clarify the current definition of ARDS, it is not without its shortcomings, particularly because it does not delineate the cause of hypoxemia (i.e., alveolar damage) or clearly establish the presence of increased permeability. Unfortunately, easily employed tests for microvascular permeability are not yet available at the bedside. It would also be impractical to base the clinical definition of ARDS upon histologic findings given the often critical condition of patients and their poor candidacy for biopsy by the time of clinical diagnosis. Nevertheless, when comparing prior clinical definitions to the gold standard definition of ARDS (histopathology from surgical lung biopsy or autopsy), the clinical definition has traditionally fallen short in recognizing all cases of ARDS [13,19].
HISTOPATHOLOGY

Despite having many different potential etiologies [20,21], the histologic findings of ARDS are fundamentally uniform and are collectively described by the term diffuse alveolar damage (DAD) [22]. DAD represents a continuum of changes that can be temporally divided into exudative, proliferative, and fibrotic phases [22], between which considerable overlap exists. The exudative phase of DAD is the earliest phase, during which clinical symptoms first develop and lung mechanical changes become manifest. This phase typically occupies the first week and is characterized by epithelial and endothelial cell death, neutrophil sequestration, platelet-fibrin thrombi, interstitial edema, and exudates within the airspaces, which consist of fluid, protein, and cellular debris [22]. These exudates compact into dense, protein-rich hyaline membranes that stain strongly with eosin and line the alveoli and alveolar ducts (Fig. 163.1A). During protracted injury, the proliferative phase ensues and is characterized by organization of the intra-alveolar exudates and proliferation of type II alveolar cells, fibroblasts, and myofibroblasts. During this phase, it is common to find areas of squamous metaplasia and granulation tissue occluding alveolar ducts in a manner similar to that of organizing pneumonia (Fig.163.1B) [23].

FIGURE 163.1 A: Histologic lung specimen from
ARDS patient, showing red blood cells and neutrophils within the alveolar space and characteristic hyaline membranes (arrow) consistent with diagnosis of diffuse alveolar damage (DAD). B: Distal airspace granulation tissue (asterisks) consistent with organizing pneumonia (hematoxylin and eosin stained, 60X).

Images were graciously provided by Dr. Martha Warnock.

The fibrotic phase has classically been considered the later phase of remodeling that occurs in patients whose disease course persists beyond 2 to 3 weeks [22], but studies suggest an increase in the fibrotic response to ARDS as early as 24 hours from presentation [24], and histologic evidence of fibrosis can be seen within days of presentation of some patients [25]. Because such overlap exists between the fibrotic and proliferative phases, the two are often described together as the fibroproliferative phase, and there is evidence that increased fibroproliferative signaling and fibrosis predict worse outcomes [24].
RADIOGRAPHIC FINDINGS

In the most recent Berlin definition of ARDS, the expert panel chose to retain the AECC criteria of bilateral airspace opacities consistent with pulmonary edema, but also allowed for this criteria to be recognized on computed tomography (CT) imaging, as well [14]. These infiltrates will often initially appear as heterogeneous opacities, but later become more homogeneous over hours to days [26] (see Fig. 163.2A). Although some have recommended using criteria such as cardiac silhouette size and vascular pedicle width to differentiate cardiogenic from noncardiogenic edema, this differentiation has proven to be frequently impossible [27]. Furthermore, the seemingly straightforward interpretation of bilateral infiltrates can be obscured by factors such as atelectasis, effusions, or isolated lower lobe involvement, all of which contribute to low interobserver agreement [12,28]. Therefore, the newer diagnostic criteria further require that the bilateral airspace opacities are not explained by effusion, lobar collapse, or nodules [13,14].

Prior to CT scanning, the pulmonary edema seen on chest radiograph was widely believed to be a diffuse process. However, CT imaging has demonstrated the distribution of ARDS to oftentimes be heterogeneous and patchy, with areas of normal-appearing, aerated lung interspersed among areas of mixed ground glass opacity and consolidation, the latter being concentrated in the more gravitationally dependent regions of the lung [27] (see Fig. 163.2B and C). Despite this pattern, a recent study using positron emission tomography (PET) to map cellular metabolic activity demonstrated that diffuse inflammatory change can be detected even in areas of the lung that appear spared radiographically [29]. Some investigators have also used PET imaging and magnetic resonance imaging (MRI) to estimate pulmonary microvascular leak and assist in the differentiation between high permeability and hydrostatic pulmonary edema [30,31], but these methods have yet to be adopted in clinical practice. One recent study demonstrated the clinical value of performing focused bedside thoracic and cardiac ultrasonography, using the presence or absence of B lines, left-sided pleural effusion, vena cava diameter, and left ventricular dysfunction to differentiate cardiogenic pulmonary edema (CPE), ARDS, and miscellaneous causes of acute hypoxic respiratory failure from one another [32]. While the clinical utility of this tool is not widespread at this time, for those readers interested in learning more about the utility of point of care critical care ultrasonography or guidance in its use, a section has been added on its use at the end of this chapter.
A plain chest radiograph from a patient with ARDS is shown in A. Computed tomography images of the chest from patients with ARDS are shown in B, C, and D. B and C: Diffuse patchy regions of consolidation with a predominance of ground glass infiltrates. D: More severe disease with a predominance of dense consolidation, a large right pleural effusion, and sequelae of barotrauma, with pneumatoceles throughout both lungs and a persistent pneumothorax on the left despite two chest tubes (one shown in cross section and one longitudinally).
The estimated incidence of ARDS worldwide has been variable in the past because of its wide range of causes and previously nonuniform definition. The first estimate by the National Institutes of Health (NIH) projected an annual incidence of 75 cases per 100,000 in the US, but subsequent studies reported estimates between 1.3 and 22 per 100,000 person years, depending on population studied [33]. A much larger pool of prospective cases from the NHLBI-sponsored ARDS Network yielded a conservative estimate of 64.2 cases per 100,000 person years [33]. A more recent and significantly larger prospective cohort from King County in Washington State estimated an annual incidence of 78.9 cases per 100,000 person years, in keeping with the ARDS Network and original NIH estimates, and felt likely to be the most accurate estimate to date for incidence in the US [9]. This incidence, combined with a high morbidity, creates a substantial burden of cost to health care. ICU care accounts for approximately 13% of hospital costs in the US, and almost one-third of that is attributable to patients who require mechanical ventilation [34,35].

In patients at risk of developing ARDS, the onset is typically swift, with a median onset between 1 and 2 days [13,36]. Onset is less than 24 hours in just over half of patients with ARDS due to sepsis and in about one-third of patients with ARDS from trauma, and within 5 days of any insult in over 90% of all patients that develop ARDS [13]. The known causes and risk factors for the development of ARDS have been well characterized [20,21] (see Table 163.1) and can be categorized as ensuing from either direct or indirect injury to the lung [20,25]. This differentiation is justified by the observed physiologic differences between direct and indirect ARDS and the differing outcomes associated with each cause [9]. It is now well established that sepsis is the most commonly identified cause of ARDS and is associated with the worst outcomes overall [9,18], while trauma-related ARDS has a significantly lower mortality [9,37]. These differences between mortality rates may in part be caused by differences in pathogenesis [37]. Other factors that confer risk for the development of ARDS include a history of alcohol abuse, recent chemotherapy, delayed resuscitation and antimicrobial therapy, smoking, and transfusion with blood products [38,39], particularly fresh frozen plasma and platelets [40]. Curiously, among those at clinical risk for developing ARDS, the diagnosis of diabetes mellitus has been shown to confer protection from ARDS, providing about half the relative risk as that of nondiabetic patients [38].

PATHOGENESIS

In parallel with its predominant pathologic findings on histology, ARDS is, first and foremost, a condition triggered by injury to the alveolar epithelium and capillary endothelium. The insult can be initially isolated either to the epithelium, as in the case of aspiration, or to the endothelium, as in most forms of indirect ARDS, such as sepsis. However, injury is generally detected in both the endothelium and epithelium by the time of diagnosis [22]. This injury invariably leads to a leakage into the alveolar space of plasma proteins that in turn activate procoagulant and proinflammatory pathways, leading to the fibrinous and purulent exudates seen on histology. Through increased transcription and release of proinflammatory cytokines, and an increased expression of cell surface adhesion molecules, a profound acute inflammatory response ensues, with epithelial cell necrosis and a robust recruitment of neutrophils [25,39]. The increased expression of tissue factor (TF) and other procoagulant factors ultimately leads to coagulation within the microvasculature and airspaces, accompanied by a suppression of fibrinolysis, which helps perpetuate the microthrombi and fibrinous exudates that are pathognomonic for ARDS [25].

Injury to the alveolar epithelium plays a critical role for the pathogenesis of ARDS. One well-characterized marker of epithelial injury, the receptor of advanced glycosylation end-product (RAGE), found to be highly expressed on type I alveolar epithelial cells, can be detected in high abundance in the edema fluid and plasma of patients with ARDS [41]. In fact, elevated plasma levels of RAGE were shown to predict a longer ICU length of stay and duration of mechanical ventilation for patients at risk of ARDS following heart–lung transplantation [42]. Through epithelial cell necrosis and the loss of tight junctions and barrier function, plasma proteins and edema fluid seep into the alveolar space, leading to increased shunt fraction, higher alveolar surface tension, and a greater propensity for alveolar collapse. Clearance of both protein and fluid is crucial to the resolution of ARDS. Indeed, a greater alveolar fluid clearance (AFC) rate is associated with fewer days of mechanical ventilation and lower mortality among patients with ARDS [43]. On the other side of the alveolar capillary interface, injury to the endothelium results in increased permeability, release of inflammatory molecules, expression of cell adhesion molecules, and activation of procoagulant pathways. Increased microvascular permeability has been widely demonstrated among those with ARDS [41], but this may be caused more by a functional alteration or activation of intact endothelium than by actual cell lysis or necrosis. Conditions such as sepsis and bacteremia can
activate endothelial cells to release von Willebrand factor (vWF), increase surface expression of potent adhesion molecules known as selectins, and increase expression of intracellular adhesion molecule-1, which helps to bind neutrophils and facilitate their transmigration across the endothelial barrier [41]. The important role of endothelial activation for ARDS is highlighted by the finding that elevated plasma levels of vWF have been shown to predict the development of ARDS among patients at risk and are associated with worse outcomes for patients with established ARDS [41]. Recently, the role of another endothelial cell activation marker, Angiopoietin-2 (Ang-2), has been recognized as a potential marker of capillary leak and ARDS severity. Released from endothelial cells in response to multiple activating insults, Ang-2 can lead to increased vascular permeability and adhesion of circulating neutrophils [41], and increased circulating levels have been correlated with an increased risk of developing and dying from ARDS [44,45].

The role of the neutrophil in ARDS pathogenesis has been widely accepted for years. Although the neutrophil is not essential for the development of ARDS, as evidenced by the development of ARDS in the setting of neutropenia, its course can often worsen during the recovery from neutropenia and after administration of the neutrophil growth and releasing factor, G-CSF [46]. Recently, experimental animal models have led to mounting evidence for a complex interplay between platelets and neutrophils during their adhesion to the endothelium, with both platelet depletion and pharmacologic inhibition of platelet function mitigating neutrophil recruitment and ARDS severity [47,48]. In support of these findings, one single center observational study has since demonstrated prehospital antiplatelet therapy to independently predict a reduced risk for the development of ARDS [49], but a secondary analysis of a separate cohort of patients failed to find the same association between prehospital aspirin use and development of ARDS [36,50]. Nevertheless, these findings have helped foster interest in a current ongoing multicenter trial investigating the role of aspirin in the prevention of ARDS (NCT01504867).

Activated leukocytes and endothelial cells also contribute to dysregulated intravascular and extravascular coagulation [25]. Extravascular alveolar fibrin arising from increased procoagulant activity and impaired fibrinolysis has been well described for ARDS [41]. Fibrin formation and clearance in the lung is in part governed by the differential activity of fibrinolysis promoters and inhibitors. At the point of coagulation and fibrin generation, TF has received notable attention because of its known interaction with factor VIIa and downstream generation of thrombin. TF expression is increased on the surface of alveolar epithelial cells and macrophages among patients with ARDS and is accompanied by increased procoagulant activity in the edema fluid
but TF has not been shown to be useful for diagnosis [41]. On the other hand, Plasminogen activator inhibitor-1 (PAI-1) can prevent fibrinolysis via direct binding and inhibition of plasminogen activators. Elevated plasma levels of PAI-1 and reduced plasma levels of the endogenous anticoagulant protein C have both been shown to discriminate between acute cardiogenic edema and ARDS and to be independent risk factors for mortality and adverse clinical outcomes [41,52]. Numerous additional pathways have been implicated in the pathogenesis of ALI, but an attempt to cover each in depth would extend beyond the intended breadth of this chapter.
Because of the accumulation of extravascular lung water (i.e., pulmonary edema), the physiologic derangements of ALI invariably manifest as refractory hypoxemia, decreased respiratory compliance, and a propensity for alveolar closure [25]. As alveolar edema fluid and protein accumulate within the alveoli, physiologic shunt develops as blood flows through capillary units to alveoli that are either filled with fluid or have collapsed from increased surface tension (see Fig. 163.3A). Hypoxic vasoconstriction, the normal autoregulatory reflex that helps match ventilation and perfusion by shunting capillary blood flow away from poorly ventilated regions of the lung, is severely impaired within the diseased regions of the lung, leading to an imbalance and increased blood flow to poorly ventilated lung regions [53]. Increased vasoconstriction and scattered microthrombi within well-ventilated lung regions contribute to physiologic dead space or “wasted ventilation” via diminished blood flow to aerated lung [53] (see Fig. 163.3B). The combined effects of these derangements result in refractory hypoxemia and increased minute ventilation requirements, which explain the often challenging demands of managing these patients in the intensive care unit.

**FIGURE 163.3**  A: The edema-fluid-filled alveolus and a neighboring collapsed alveolus, both with unrestricted blood flow, contributing to physiologic shunt. Double headed arrow represents potential for fluid-filled alveolus to collapse and reexpand during normal tidal ventilation. B: The effect of a microthrombus (black oval) obstructing blood flow to a functioning alveolus, contributing to physiologic dead space.
Overall, the average pulmonary vascular resistance is commonly elevated in patients with ARDS [25] likely because of a reduction in total luminal diameter of the vascular bed from vasoconstriction and thrombotic obstruction. This in turn leads to the common finding of pulmonary hypertension among these patients, which can alter right ventricular loading and function and predicts higher mortality in afflicted patients [54]. Because elevated pulmonary artery pressures could, in theory, contribute to increased pulmonary edema and right heart strain, it is unclear whether pulmonary hypertension is directly contributing to mortality or simply a marker of disease severity.

The mechanical characteristics of ARDS manifest primarily as a decrease of respiratory compliance. This is primarily caused by a decrease in compliance of the lung, particularly in the more direct forms of ARDS such as pneumonia. However, contribution from the chest wall and abdominal compartment can be significant under conditions such as trauma and peritonitis [55]. The reduction of lung compliance reflects the collective contribution of changes in the intrinsic elastic properties of the remaining aerated lung and a reduction in resting lung volume via alveolar flooding and collapse. The increased elastic properties of the aerated lung result from increased tissue stiffness due to interstitial edema and increased alveolar surface tension, the result of increased surface forces generated by a greater abundance of alveolar lining fluid and a decrease in surfactant activity [25]. This loss of surfactant activity is believed to result from inhibitory binding of surfactant by plasma proteins and cholesterol, and decreased production of functionally active surfactant by type II pneumocytes [56]. Furthermore, the biomechanical effects of mechanical ventilation alone can alter the structure and biophysical properties of surfactant [57].

Lower resting lung volumes in ARDS result from persistently fluid-filled or collapsed alveoli, leading to what has been colloquially referred to as “baby lung” [58]. The affected regions of the lungs are often so diseased that they may remain fluid filled or collapsed throughout each tidal inflation [59] and hence contribute negligibly to compliance. As a result, tidal volumes delivered to the heterogeneously fluid-filled and atelectatic lung are shunted preferentially to more compliant, aerated regions of the lung. This is one of the main postulated mechanisms through which mechanical ventilation can overdistend and injure the remaining regions of “normal lung” and lead to ventilator-induced lung injury (VILI) [60,61].
MANAGEMENT

Mechanical Ventilation

Mechanical Ventilation and Low Tidal Volumes

The early presentation of ARDS is chiefly characterized by hypoxemic respiratory failure and the almost invariable need for support with mechanical ventilation, but this may be changing in the wake of high-flow nasal cannula oxygen delivery [62]. Because the greatest danger posed to patients with ARDS is the development of multiorgan failure [63], establishing supportive ventilation modes that optimize hemodynamic function and oxygen delivery remains an important objective in the management of these patients. Prior to the late 1960s, endotracheal intubation and positive pressure mechanical ventilation were primarily used for supporting patients during general anesthesia. It was during this time that investigators first noted that larger tidal volumes could reduce the shunt associated with atelectasis during general anesthesia, and because many of the techniques used for the support of patients with acute respiratory failure were originally adopted from general anesthesia practice, employing tidal volumes of 10 to 15 mg per kg became the standard for improving oxygenation and ventilation for patients with ARDS [1,64]. We now know that idealized oxygenation and normal physiologic pH and PaCO$_2$ can come at a cost when employing higher tidal volumes in patients with ARDS. After the discovery that lung injury pathologically resembling ARDS could be induced de novo in animal models through lung overdistension with higher tidal volumes [25,60], small retrospective and prospective uncontrolled trials were completed that suggested a benefit from limiting tidal volume and peak airway pressures in patients with ARDS [25]. Numerous larger, randomized trials comparing traditional and lower tidal volumes have since been conducted, each trial differing in its methodology and results. The largest randomized, multicenter trial to date, conducted by the ARDS Network, ultimately demonstrated significantly lower mortality among those assigned to a tidal volume of 6 mL per kg of predicted ideal body weight and a target plateau pressure of 30 cm H$_2$O or less (mortality 31.0%) as opposed to a tidal volume of 12 mL per kg and a target plateau pressure less than 50 cm H$_2$O (mortality 39.8%) [1]. Following this landmark study, controversy arose regarding whether “artificially high” tidal volumes drove the benefits observed in the trial, but this assertion was not supported by data demonstrating consistent use of tidal volumes far
in excess of 10 cc per kg in clinical practice prior to and long after the study was published [25,65,66]. Indeed, even years later, there was sufficient variation in practice among four hospitals in Baltimore to power a statistically significant 18% relative increase in observed mortality for each 1 mL per kg increase in average tidal volume delivered [67,68]. All this has led professional societies to recommend the use of lower tidal volumes at goal plateau pressures less than 30 cm H₂O in patients with established ARDS [69]. Going a step further, there is now evidence that the benefits of low tidal volumes are exclusive of simply maintaining a plateau pressure less than 30 cm H₂O, but added benefit is also gained by keeping plateau pressures substantially lower than 30 cm H₂O [70,71], leading some experts to suggest maintaining the lowest tidal volume and plateau pressure that can safely be achieved [67].

Because calculation of tidal volume based on total body weight may be partly responsible for the documented underuse of lower tidal volumes for patients with ARDS [65], the importance of using predicted ideal body weight (IBW), based upon measured height and sex, cannot be overstressed. IBW (in kg) for males is calculated as 50 + 0.91[(height in cm) − 152.4], and for females as 45.5 + 0.91[(height in cm) − 152.4] [1].

To achieve these practice guidelines, a strategy of “permissive hypercapnia” is often needed, in which a reduction in minute volume and an ensuing increase in PaCO₂ is tolerated in order to achieve lower target tidal volumes and airway pressures [72]. Numerous experimental animal models have actually demonstrated a protective effect of hypercapnic acidosis (HCA) that is abolished by buffering with bicarbonate solution [72], but other work suggests that HCA may worsen ARDS [73,74]. A recent secondary analysis of the ARDS Network study demonstrated a reduced 28-day mortality conferred by HCA in the 12 cc per kg group, but a similar benefit was not found for the 6 mL per kg group, suggesting that permissive hypercapnia is at the very least safe, and possibly beneficial [67,72,75]. These noted benefits, along with concerns that bicarbonate infusion may actually worsen intracellular acidosis, have led some experts to dissuade practitioners from buffering HCA with bicarbonate unless there is a clear rationale for doing so [67,72].

To better understand the protection conferred by low tidal volumes, investigators have studied how this strategy modulates the inflammatory cascades associated with ARDS and VILI. Evidence now exists to support the theory that low tidal volume ventilation improves outcomes at least in part through reduced activation of the inflammatory cascades associated
with VILI and multiorgan failure. Among patients enrolled in the ARDS Network trial of low tidal volume, it was found that higher plasma levels of soluble receptors for tumor necrosis factor-α (TNF-α) were associated with higher mortality and fewer organ-failure–free days \[76\]. Furthermore, the lower tidal volume strategy was associated with lower levels of soluble TNF-α receptor I \[76\]. Elevated plasma levels of interleukin (IL)-6, 8, and 10 were also linked to increased mortality, while lower tidal volume was associated with a greater decline in IL-6 and IL-8 levels by day 3 of enrollment \[77\].

Currently, no firm guidelines exist regarding patients without established ARDS (with the exception of sepsis \[69\]), but there is now mounting clinical evidence that a low tidal volume strategy can help prevent progression to ARDS in patients at risk \[78–80\] and is also of clinical benefit in intermediate to high-risk patients undergoing major abdominal surgery \[81\]. Although data suggest that tidal volumes lower than 6 mL per kg may confer even greater protection from VILI \[82\], there is no general consensus regarding this practice. However, the authors note that in the original ARDS Network trial, the lower tidal volume assignment started with a goal of 6 mL per kg, but tidal volumes were oftentimes adjusted to as low as 4 mL per kg to maintain plateau pressures less than 30 cm H₂O \[1\], and some experts \[67\] argue that practitioners should target the lowest tidal volume and plateau pressures that can safely be achieved.

**Recruitment**

The physiologic abnormalities in ARDS can, for some patients, be reversed by a recruitment maneuver (RM), typically delivered as a sustained or stepwise deep inflation with the intention of reopening collapsed regions of the lung \[67,83\]. However, because of the unusually high surface tension within affected alveoli, the benefit is often transient, especially if not followed by sufficiently high levels of PEEP \[84\]. The rationale for using RMs is to recruit otherwise atelectatic lung to improve end-expiratory lung volume, and in turn mitigate the development of additional VILI accruing from atelectasis and cyclic alveolar reexpansion at end-expiration \[61,83\]. On the other hand, periodic RMs can promote hypotension by limiting venous preload return and cardiac output \[83\], and could conceivably even contribute to lung injury through excessive overdistension or repeated opening of collapsed lung \[83,85\].

Clinical studies have yielded highly variable results with regard to the impact of RMs on important outcomes. Although a trial from the Lung Open Ventilation Study (LOVS) group demonstrated a reduction in severe hypoxemia and need for rescue therapies with an “open lung” approach of combined RMs and higher PEEP, it did not demonstrate any
reduction in all-cause mortality [86]. In a follow-up meta-analysis of 40 trials, which included the LOVS study and three other randomized controlled trials, authors found that, in general, ARDS patients receiving RMs exhibit a significant but short-lived improvement in oxygenation with often transient and self-limited hypotension and desaturation during the RM [83]. These mixed findings have led these and other experts to conclude that RMs can neither be recommended nor discouraged for all patients but can be considered on an individualized basis for patients with life-threatening hypoxemia [67,83,87].

Positive End-Expiratory Pressure

PEEP is the most widely employed strategy shown to retard alveolar derecruitment in the injured lung. Several studies have demonstrated the ability of PEEP to prevent or delay alveolar derecruitment and attenuate VILI [88,89]. However, the protective effect of higher PEEP was called into doubt after a multicenter randomized trial failed to demonstrate an improvement in outcomes using a higher PEEP strategy during low tidal volume ventilation in ALI patients [90]. In this trial, higher levels of PEEP were arbitrarily coupled to each stepwise increment in FiO₂ requirement during low tidal volume ventilation [90]. The study failed to demonstrate any benefit in mortality or ventilator-free days with higher PEEP [90], but potential underpowering of this study has left room for continued debate [91]. Additionally, since the amount of recruitable lung varies significantly among ARDS patients, some have suggested that setting PEEP levels without first determining the level of recruitable lung may offset the potential benefits of PEEP [88,89]. In another randomized trial from the Expiratory Pressure (ExPress) Study Group, where the selection of PEEP was more “patient directed” and set at a level required to maintain plateau pressures of 28 to 30 cm H₂O, the higher PEEP strategy again failed to demonstrate a reduction in mortality, but did demonstrate lasting improvements in oxygenation and compliance, an increase in ventilator-free and organ failure–free days, and a trend toward improved survival in more severe ARDS [92].

Since these trials, several post hoc analyses and meta-analyses have yielded a predominance of findings that suggest the use of higher PEEP to be of greater benefit in patients with moderate-to-severe ARDS, and of less benefit (or potential harm) in those with mild ARDS [89,93,94]. A larger meta-analysis by Briel and colleagues demonstrated a 10% relative
risk reduction in in-hospital mortality with higher PEEP in moderate-to-severe ARDS but a trend toward increased mortality from higher PEEP in mild ARDS [93]. A subsequent meta-analysis concluded no benefit for mortality from higher PEEP [95], but experts have pointed out the failure of this analysis to stratify patients on the basis of disease severity [89,95]. A Cochrane review in 2013 also demonstrated no benefit with higher PEEP applied broadly, but a subgroup analysis supported the findings of Briel and colleagues favoring higher PEEP in moderate-to-severe ARDS [94]. Yet another secondary analysis of findings from the LOVS and ExPress trials found that among patients whose PEEP had been increased following randomization, a positive oxygenation response to PEEP (an increase of 25 mm Hg or greater in their P/F ratio) was associated with lower mortality, and the association was stronger in patients with more severe disease [96]. This could simply imply that patients with more “recruitable” lung have better outcomes, but these findings led the authors to speculate that this improved oxygenation response to PEEP may help better predict who will benefit from higher PEEP [96]. Alternatively, some experts have concluded that a more practical, bedside imaging modality for assessing lung recruitment from added PEEP is needed [88]. Others have shown that more directly targeting PEEP to transpulmonary pressure by measuring esophageal pressures may be a safer and more effective means of determining optimal PEEP [97], and a larger follow-up randomized trial of esophageal pressure–directed PEEP is currently enrolling patients with moderate-to-severe ARDS (clinicaltrials.gov NCT01681225) [89].

High-Frequency Ventilation and Extracorporeal Membrane Oxygenation

With the data demonstrating a reduction in mortality with low tidal volumes, and animal studies showing that even lower tidal volumes offer additional protection [82], high frequency oscillation ventilation (HFOV), with tidal volumes equal to or less than dead space, would seem to be an ideal mechanical ventilation strategy for ARDS. Early investigations in the use of HFOV in adults with ARDS yielded mixed results [60,98], and a meta-analysis suggested that HFOV may provide a reduced risk of mortality when compared to conventional mechanical ventilation, but this benefit was mitigated when comparing HFOV to mandated low tidal volume ventilation [98]. However, two large randomized multicenter trials have since compared HFOV to a conventional low tidal volume strategy in adult patients with moderate-to-severe ARDS. One demonstrated no benefit in mortality or ventilator-free days from HFOV over conventional low tidal volume ventilation [99]. The other was terminated early on the basis of increased mortality in the HFOV group.
These results have led experts to clearly favor conventional low tidal volume ventilation over HFOV as first-line support for adult patients with ARDS [89], but they have not entirely excluded the option of turning to HFOV for patients failing conventional therapy in centers with expertise in safe HFOV delivery [60]. Extracorporeal membrane oxygenation (ECMO), used alone or in combination with protective ventilation, uses cardiopulmonary bypass to facilitate gas exchange while minimizing ventilation of the lung to limit barriers to healing. Despite demonstrated efficacy in neonates with severe respiratory distress syndrome, nonrandomized observational studies provided conflicting results regarding survival benefit of ECMO in adult ARDS, and earlier randomized trials were negative with high rates of mortality in both treatment assignments [89,101]. The largest randomized controlled trial to date in ECMO for severe adult ARDS demonstrated an improvement in 6-month survival without disability for the group that was transferred to an ECMO center for consideration of ECMO, when compared to the conventional treatment group [102]. However, only 76% of patients transferred to the specialized ECMO center actually received ECMO, and only 70% of patients assigned to the conventional treatment group received low tidal volume ventilation per protocol (vs. 93% in the ECMO group) [102]. This has led many experts to conclude that the study really only demonstrated a benefit in being transferred to a specialized ECMO-capable center [89,101].

Noninvasive and Partial Support Ventilation

Noninvasive ventilation (NIV) and partial support invasive ventilation modes, such as pressure support ventilation, allow for patient triggering and cycling of breaths, resulting in more spontaneous breathing. The potential advantages of spontaneous breathing over controlled mechanical ventilation include improved patient–ventilator synchrony, lower sedation requirements, and improved hemodynamics and ventilation/perfusion (V. a/ Q. ) matching [67]. Partial assist modes of ventilation can still effectively help unload respiratory workload, while helping to improve aeration and ventilation/perfusion matching within dependent lung regions, presumably because of more pronounced transpulmonary pressures generated within these regions by an actively moving diaphragm.

While many studies have demonstrated a high rate of success for preventing the need for intubation during hypoxemic respiratory failure, particularly in the setting of CPE, others have demonstrated high rates of NIV failure in patients with ARDS [103,104]. Furthermore, NIV failure has been associated with higher mortality rates (up to 64%) in patients with hypoxemic respiratory failure [105,106], leading many to urge the
need for caution in using NIV in the support of patients with ARDS [67,103]. This high rate of NIV failure among patients with acute hypoxemic respiratory failure was once again demonstrated in a recent randomized trial comparing NIV to both standard and high-flow nasal cannula oxygen delivery [62]. The study demonstrated greater patient comfort for the high-flow nasal cannula group, but the reduced frequency of the need for intubation among this group (38%) only reached statistical significance in a post hoc analysis for patients with a P:F ratio of <200 mm Hg [62]. However, the hazard ratio for death was substantially higher for both the NIV (2.50) and standard nasal cannula (2.01) groups when compared to high-flow nasal cannula [62]. Regardless, these somewhat preliminary findings suggest that high-flow nasal cannula is a clearly safe means of potentially avoiding the need for intubation and perhaps safer than NIV with respect to long-term outcomes.

Prone-Positioning

Prone-positioning was shown to improve oxygenation for patients with hypoxic respiratory failure as early as the mid-1970s [89]. Proposed mechanisms have included recruitment and improved ventilation of the previously dependent dorsal lung, and improved ventilation–perfusion matching via redirection of the gravitationally distributed perfusion toward the newly dependent (better ventilated) lung. Contrary to earlier speculation, however, prone-positioning exerts limited gravitational effects on regional perfusion in either normal or injured lung [107], but it can improve ventilation within previously dependent dorsal lung regions [108] via regional changes in chest wall mechanics and reduced lung compression by the heart and mediastinum [89].

Despite these known physiologic benefits, most of the earlier clinical trials demonstrated improved oxygenation with prone-positioning, yet no reduction in mortality [109–111]. However, none of these earlier clinical trials were coupled to IBW-determined low tidal volume ventilation. Post hoc analysis of data from the first of these trials suggested an early survival advantage in the most severe subgroup of patients [109], a finding supported by subsequent studies [110]. Since these earlier negative trials were completed, the Proning Severe ARDS Patients (PROSEVA) study group concluded a multicenter randomized trial that demonstrated a significant reduction in mortality among patients with more severe (P:F ratio < 150) ARDS [4]. The protocol directed 16 consecutive hours of prone position for at least 28 days, was coupled with
6 mL per kg IBW tidal volumes, and a target plateau pressure less than 30 cm H$_2$O, and it demonstrated a significant reduction in 28-day mortality (hazard ratio for death 0.39) and 90-day mortality (hazard ratio 0.44) [4]. Since then, a meta-analysis examining combined data from these and other trials found a significant benefit from prone-positioning when examining patients with tidal volumes <8 mL per kg IBW, but not with tidal volumes >8 mL per kg [112], suggesting that the benefit of proning may extend beyond the most severe of ARDS patients when coupled to a low tidal volume strategy. Nevertheless, given the high reported rates of complications associated with prone-positioning [111,113], experts have concluded that prone-positioning should be limited to patients with severe hypoxemia and undertaken only in high expertise centers with experience in safe technique.

**Fluid Management**

Since pulmonary edema is the hallmark of ARDS, it seems reasonable to keep patients relatively “dry” in their total fluid volume. However, because the development of multiple organ dysfunction syndrome (MODS) increases mortality from ARDS, the critical maintenance of adequate peripheral perfusion may require liberal administration of intravenous fluid, at least initially. Earlier studies demonstrated an improvement of physiologic parameters with diuresis guided with and without vascular pressure measurement or by measurement of extravascular lung water [25]. Diuretic therapy with combined albumin and furosemide has been shown to improve oxygenation and hemodynamics in hypoproteinemic ARDS patients but did not reduce mortality [114]. The NHLBI ARDS Network trial of conservative versus liberal fluid management demonstrated no difference in 60-day mortality between the two different strategies [115]. However, subjects in the conservative strategy group had a lower 7-day cumulative fluid balance with improved lung function and a reduced duration of mechanical ventilation without an increase in nonpulmonary organ failure [115], providing some evidence to support the view that a conservatively lower fluid balance is safe and may provide more favorable outcomes. The caveats to these conclusions include barriers to generalizability of the findings in the setting of multiple exclusion factors (including renal failure and heart failure), and that all patients were allowed to receive a liberal fluid resuscitation strategy (if deemed clinically necessary), for on average up to the first 43 hours from their presentation, and most had optimized hemodynamics by the time of enrollment [116]. Further controversy exists in respect of what method should be used to guide fluid management. Whether the indwelling pulmonary artery (PA) catheter is vital to the management of ARDS depends on two important
considerations. First, optimal fluid balance must be crucial to preventing the progression of lung injury. Evidence linking a more positive fluid balance to the development of ARDS [117] and evidence linking increased extravascular lung water to the development of MODS and ARDS [118,119] support this first requisite justification [120,121]. Second, however, PA catheters must provide a critical and unique understanding of this balance that sufficiently and appropriately modifies clinical practice, and this has yet to be proven. Most recent evidence from the ARDS Network trial of fluid management suggests that PA catheter–guided therapy does not improve survival in ARDS over therapy guided by simple central venous pressure (CVP) alone [122], but data supporting the use of CVP to guide therapy are also equally limited [121,123]. In fact, CVP has been repeatedly demonstrated to be an unreliable index of cardiac preload and fluid responsiveness [121,123]. Thus, with the wider adoption of bedside ultrasonography in critical care, numerous additional noninvasive bedside measurements have been used to predict fluid responsiveness during resuscitation [124], with the intent of avoiding overresuscitation in patients at risk for developing ARDS [125,126]. There are now multiple techniques currently being used to help guide resuscitation and limit volume overloading, including but not limited to echocardiographic measures of stroke volume variability and inferior vena cava distensibility, peripheral pulse pressure variation, and response to passive leg raise [124,125,127], all of which have demonstrated reasonably high sensitivity and specificity in predicting fluid responsiveness, but none of which have yet to contribute to a management strategy shown to improve outcomes.

Pharmacologic Interventions

As in any other medical disease or syndrome, it would seem that the “Holy Grail” among clinicians is the discovery of some novel agent that can either break the cycle of disease pathogenesis or help restore physiologic homeostasis and reduce disease severity and morbidity. The field of pharmacologic intervention has been exhaustively explored in the field of ALI, often yielding promising results in animal models and periodically demonstrating modest improvements in lung function and oxygenation in patients, but rarely translating into improved outcomes.

Pulmonary Vasodilators

Given the advanced endothelial injury, physiologic shunt, and commonly observed pulmonary hypertension in ARDS, therapeutic benefit of pharmacologic pulmonary vasodilation has been studied with a focus on inhaled nitric oxide, iNO. Unfortunately, despite several clinical trials
demonstrating improvements of physiologic responses, including vasodilation and oxygenation, there has been no consistent improvement in mortality. In addition, adverse consequences, including dose-dependent methemoglobinemia, pulmonary hypertension, and renal impairment, have been identified [128–130], so iNO is not currently recommended for the treatment of ARDS, although it may still be used as a rescue therapy at some centers.

**Surfactant Replacement**

Not long after ALI was first described [131], investigators demonstrated a reduction in the amount of surfactant retrieved from the lung and a derangement in the retrieved surfactant’s biophysical properties [132]. Since then, numerous studies have supported these findings. The fundamental rationale for surfactant replacement is to help restore the natural surfactant film and reduce surface tension at the air–liquid interface, thus reducing the tendency for alveolar collapse and improving oxygenation through a reduction in shunt. The evidence in support of surfactant replacement therapy for neonatal RDS is abundant, but results in adults with ARDS have been less promising [130,133]. Despite promising results of small trials, several larger randomized phase 3 trials in ARDS failed to demonstrate any reduction in mortality [56,134]. Some have speculated that the failure to demonstrate an improvement in mortality results from the lack of a direct relationship between mortality and severity of respiratory failure, the intricacies of surfactant administration, and/or its potential inactivation by plasma proteins following delivery [135].

**Corticosteroids**

Given the well-characterized acute inflammatory response of ARDS, considerable effort has been spent determining the therapeutic role of corticosteroid therapy for the early and late treatment of this condition. Numerous uncontrolled trials had initially suggested a potential benefit of corticosteroids, and the first randomized controlled trial of corticosteroids for late ARDS demonstrated improved lung injury scores and oxygenation, decreased multiorgan dysfunction scores, and reduced ICU and in-hospital mortality in the group receiving steroids [136], but this study drew criticism for its small size and baseline differences between the treatment groups. Subsequently, a significantly larger NHLBI-sponsored multicenter trial completed by the ARDS Network
exploring the use of corticosteroids for late persistent ARDS demonstrated more ventilator-free days and improved oxygenation for the group treated with methylprednisolone compared to placebo, but no reduction in 60-day mortality [137]. There was, however, an increase in neuromuscular weakness, and a higher 60- and 180-day mortality was observed when steroid therapy was initiated after 14 days of onset, suggesting a serious risk from this therapy for late ARDS.

Initial studies of steroids for early ARDS did not demonstrate benefit, but a more recent study [138] suggested an improvement in ICU mortality. However, the study was small, and concerns were raised regarding imbalances among the treatment arms. Several meta-analyses of the effects of glucocorticoids on ARDS mortality have come to different conclusions, adding to the challenges in establishing guidelines [139–142].

Anticoagulation/Fibrinolysis

The importance of microvascular coagulation and thrombosis in ARDS is underscored by the physiologic dead space, or “wasted ventilation,” observed in ARDS patients [143]. Minimizing microvascular thrombosis could conceivably improve oxygenation through improved ventilation–perfusion matching [144] and increase survival through prevention of multiorgan failure [145]. Despite promising results in a rat model [146], the most recent phase II clinical trial of the endogenous anticoagulant activated protein C (APC) in ARDS failed to demonstrate a reduction in ventilator-free days with the use of APC [147]. Critics expressed concern about the study’s statistical power and a priori likelihood of success [148], but in a similar vein, despite promising animal studies [144,149], a multicenter phase II trial of tissue factor inhibitor (site-inactivated VIIa) in ARDS was terminated prematurely because of an increased risk of adverse bleeding and a higher projected mortality rate in the high-dose treatment arm [8]. Thus, it seems that the benefits of potent anticoagulation in ARDS may ultimately be outweighed by risks of adverse bleeding.

β-Agonists

As discussed in the pathogenesis section, AFC often remains intact in the setting of injury. AFC can be directly increased by β-agonists in animal models [150,151], presumably through upregulated activity of Na, K-ATPase at the basolateral membrane [152]. β-agonists might thus promise to have significant potential for benefit in ARDS. In animal models and clinical studies, beta-agonists have been shown to increase AFC, decrease endothelial permeability, increase surfactant secretion,
and decrease inflammation [130,153]. Early small clinical trials of β-agonists for ARDS were promising, but two large randomized multicenter clinical trials were disappointing. The Albuterol Treatment of Acute Lung Injury trial [6] was stopped for futility, and the β-agonist Lung Injury Trial 2 (BALTI-2) was stopped for safety concerns [5]. In the wake of findings, there is currently no support for the use of β-agonists in the treatment of ARDS.

However, both of these trials enrolled patients with existing lung injury, and it is possible that β-agonists could be more effective in promoting enhanced AFC if administered prior to epithelial barrier disruption. To test this hypothesis, there is currently a multicenter, placebo-controlled phase 2 trial, Lung Injury Prevention Study with Budesonide and β Agonist (LIPS-B), enrolling patients at risk for ARDS. Patients will be randomized to aerosolized budesonide/formoterol versus placebo for 5 days, and the primary outcome is improvement in oxygenation (clinicaltrials.gov NCT01783821).

Nutritional Supplementation

Over the past decade, enthusiasm has arisen over the use of nutritional supplements in sepsis and ALI, particularly with the use of omega-3 fatty acids and other natural antioxidants such as vitamin E. The rationale for supplementing patients with omega-3 fatty acids, such as eicosapentaenoic acid, in the setting of inflammatory disorders comes from the notion that they can directly suppress monocyte production of inflammatory cytokines and incorporate into cell membrane phospholipids to compete with omega-6 fatty acids to promote the production of more favorable profiles of prostaglandins and leukotrienes [154].

To further understand the effects of omega-3 fatty acids alone, a phase 2 trial of 90 patients was completed but showed no benefit [155]. The ARDS Network initiated a phase 3 trial of enteral administration of omega 3 fatty acid, linolenic acid, and antioxidants (OMEGA). The trial was stopped early in view of concerns over potential harm because the treatment group had significantly fewer ventilator-free, ICU-free, and organ failure–free days [156]. Of note, in tandem with the OMEGA trial, the ARDS Network randomized patients with ARDS to low-volume trophic enteral feeds versus full enteral feeds for 6 days. There were no significant differences in ventilator-free days, 60-day mortality, or infectious complications [157].

HMG-CoA Reductase Inhibitors (the “statins”)

HMG-CoA Reductase Inhibitors (also called “statins”), a class of drugs
originally developed for the treatment of dyslipidemia and now used widely for the prevention of atherosclerosis, seemed to have significant potential for the treatment of ARDS. These drugs decreased inflammation and prevented ARDS in animal models, and also decreased both systemic and pulmonary inflammation in a human model of LPS (bacterial lipopolysaccharide) inhalation lung injury [158,159]. Studies initially suggested that statin use was associated with a decreased risk for the development of sepsis and its associated complications, including death [160], and a decreased risk for the development of ARDS [161], but the largest observational study found no protective effect for the development of ARDS associated with previous or concurrent statin use [162]. Similarly, observational studies and meta-analyses had demonstrated that patients on statins prior to hospitalization for infection had decreased morbidity and mortality, although a more recent meta-analysis [163] did not confirm those findings.

Two large randomized trials of statins in ARDS also failed to demonstrate an improvement of clinical outcomes. The larger randomized trial of rosuvastatin for patients with sepsis-associated ARDS was stopped for futility [3]. It demonstrated no improvement in the primary clinical outcome, mortality before discharge or by day 60, or in secondary endpoints, including ventilator-free days and organ failure–free days, but there was also evidence of an increase in renal and hepatic dysfunction for the treatment group. The second smaller, phase 2 multicenter, double-blinded clinical trial of simvastatin in patients with ARDS also found no difference in the primary outcome of ventilator-free days, or in the secondary outcomes of days free of nonpulmonary organ failure and 28-day mortality, but also found no difference in adverse outcomes [164].
Airway Pressure Release Ventilation (APRV)

“Airway pressure release ventilation” (APRV) is a mode of ventilation that utilizes sustained high airway pressures and spontaneous breathing to maximize lung recruitment, with brief periods of “pressure release” to facilitate ventilation while minimizing derecruitment during exhalation [165]. Proponents assert that the periods of pressure release are typically brief enough to avoid alveolar closure and reexpansion, and efficacy relies heavily on the presence of spontaneous ventilation, which is believed to generate regionally variable transpulmonary pressures that favor recruitment of dependent lung regions [166]. Another purported benefit is the potentially decreased sedation needs of patients receiving APRV, but some studies suggest this may not be the case [167]. Because a prolonged inflation pressure (i.e., \( P_{\text{high}} \)) is maintained between brief periods of pressure release, recruitment and gas exchange are often improved with typically lower maximal airway pressures than conventional ventilation [60]. However, the potential for added distension still exists while patients spontaneously breathe above the volume generated by \( P_{\text{high}} \) [60], and relatively high transpulmonary pressure swings and large expiratory tidal volumes can still occur during APRV [168] and conceivably contribute to VILI [67].

Thus far, most published experience with APRV for patients with ARDS has been in the surgical and trauma population [165,169,170]. One of the earliest randomized trials comparing APRV to synchronized intermittent mandatory ventilation (SIMV) demonstrated an improvement in physiologic outcomes but was stopped early for futility in demonstrating any improvement in mortality or ventilator-free days [171]. A retrospective study has since demonstrated an actual increase in ventilator days with APRV compared to conventional support in trauma patients with ARDS [172]. The most recent randomized control trial comparing APRV to a conventional low tidal volume strategy for adult trauma patients demonstrated equal safety profiles but also demonstrated a nonsignificant trend toward increased ventilator days and ICU length of stay in those assigned to APRV [170]. Taken together, these findings have led some experts to conclude that thus far there is insufficient evidence to support the routine use of APRV in management of ARDS [60]. On the other hand, others have been able to demonstrate that an appropriately extended duration of \( P_{\text{high}} \) (i.e., \( T_{\text{high}} \)) and an appropriately brief period of pressure release can minimize tissue strain,
respectively, through stable alveolar recruitment (homogeneous ventilation) and avoidance of alveolar collapse during exhalation [173]. These authors propose a role for APRV as a preemptive intervention for preventing the progression to ARDS in those at risk [173]. Additional work is needed in the field before APRV can be recommended over conventional low tidal volume ventilation, and it may be that the choice of one over the other will need to be tailored to the patient’s injury and lung mechanics [174].

Stem Cell Therapy

Recent attention has been given to the use of embryonic (“pluripotent”) and adult-derived (“multipotent”) stem cells and “progenitor” cells in their therapeutic potential for mitigating inflammation and enhancing tissue repair in ARDS [175]. Enthusiasm first came from findings suggesting a favorable rate of engraftment and epithelial differentiation of infused bone marrow–derived stem cells in the injured lungs of mice. More recent work suggests that the rates of stem cell engraftment and differentiation are not as robust as initially hoped [175]. The field has gained greater momentum with the discovery that the delivery of human bone marrow–derived mesenchymal stem/stromal cells (MSCs) attenuates lung injury in multiple animal models of ARDS [176], pneumonia [177,178], and VILI [179] and can even restore AFC in human lung explants [180]. As a result, there is currently an ongoing phase 2 randomized clinical trial recruiting patients to determine the safety and efficacy of a single infusion of human allogenic bone marrow–derived MSCs for ARDS (clinicaltirals.gov NCT02097641).

Keratinocyte Growth Factor

One group of investigators has demonstrated the protective effects of human bone marrow–derived MSCs to be, at least in part, related to their ability to release keratinocyte growth factor (KGF) [181], which may help promote healing through type II pneumocyte proliferation, enhanced AFC and surfactant production, and repair of oxidant injury [36]. A multicenter, placebo-controlled, phase 2 trial to determine the safety and efficacy of IV infused KGF in improving oxygenation in ARDS patients was recently completed, but the results are pending [36,182].

Neuromuscular Blockade

Clinical practice guidelines have long supported the use of neuromuscular blockade (NMB) as a means of controlling patient–ventilator synchrony, oxygenation, and ventilation [183], and studies have supported NMB for patients with ARDS as a means toward
improving oxygenation [184]. A recent multicenter randomized controlled trial conducted by the ARDS et Curarisation Systématique (ACURASYS) study group in France demonstrated a significant mortality benefit for severe ARDS from early NMB with cisatracurium [7]. The study demonstrated that NMB for 48 hours, within 48 hours of onset, in “severe” ARDS (P:F ratio < 150 mm Hg), led to a significant decrease in both 28- and 90-day mortality, without any concomitant increased risk of adverse neuromuscular weakness [7]. The benefits of NMB in ARDS, in theory, stem from a mitigation of VILI by preventing spontaneous breathing with larger than intended tidal volumes on inspiration and reduced alveolar collapse on forced exhalation [185,186]. A subsequent meta-analysis of three trials (including the ACURASYS trial) concluded that short-term NMB (48 hours cisatracurium infusion) in adult patients with ARDS reduces hospital mortality without increased risk of critical illness polyneuropathy (CIP) [187]. However, all three trials reviewed in this analysis came from the same group of investigators. Thus, some experts have urged caution in generalizing the use of NMB in all patients with ARDS [89], based upon inconsistently higher reported rates of CIP following NMB, the potential need for higher levels of sedation with NMB, and the undetermined dosing and benefit of other NMB agents.

Preemptive Intervention Protocols

The search for an effective pharmacologic intervention or management algorithm in ARDS has been extensive and has now spanned decades, but the benefits from most interventions have been limited to improvements in oxygenation or fewer days of mechanical ventilation. One important lesson from the work to date is that much of what we once thought was critical to the management of these patients, although grounded in sound rationale, is not only often ineffective but can be potentially harmful. We have, however, also become more aware of how sound basic principles of critical care, such as hand hygiene, prompt antimicrobial therapy, and protocols to prevent aspiration and nosocomial pneumonia, can substantially reduce overall morbidity in the ICU and likely contribute to the declining incidence of ARDS [36]. In fact, it has been shown that the downward trend in the incidence of ARDS over the past decade is most attributable to a decreasing incidence in hospital-acquired ARDS, with no change in the incidence of preadmission ARDS [188]. In keeping with the philosophy of preemptive intervention, other studies have demonstrated that not only is early intervention with physical therapy in mechanically ventilated patients safe and cost effective, but it can also reduce the
duration of delirium, mechanical ventilation, ICU and hospital length of stay, and promote greater functional independence by the time of discharge [189,190]. Investigators have also discovered reductions of ARDS incidence following the enforcement of conservative transfusion policies and preemptive low tidal volume ventilation in the care of patients “at risk” for the development of ARDS [78,79]. In response to this wave of preemptive interventions, the Lung Injury Prevention Study group has since bundled all of these best practices into a Checklist for Lung Injury Prevention (CLIP) [191]. In addition, investigators have developed the Lung Injury Prediction Score (LIPS), a tool that can help stratify a patient’s risk of developing ARDS and identify those most likely to benefit from preemptive intervention [192]. Although reasonably sensitive and specific, reliance on 22 different predisposing variables for calculation may limit the clinical feasibility of the LIPS, and this has helped foster interest in alternative prediction tools, such as the Early Acute Lung Injury Score, the latter being more simply based on oxygen requirement, respiratory rate, and presence/absence of immunosuppression [36,193].

PROGNOSIS AND OUTCOMES

Prognosis

While in-hospital and 28-day mortality rates can differ, depending on age, with substantially higher mortality among those over 85 years of age [9], the most currently reported mortality rates fall at around 30% [3,89]. Numerous clinical factors have been shown to predict a higher mortality rate in ARDS patients. These include male sex, African American race, advanced age, alcohol abuse, malignancy, liver disease, chronic steroid use, infection with human immunodeficiency virus, and ARDS secondary to sepsis or aspiration [18,194]. Curiously, although patients of advanced age, particularly >70 years of age, are at a significantly higher risk of death from ARDS, those who survive recover at the same rate as their younger counterparts [195,196]. Chronic alcohol abuse has been shown to increase the risk of developing not only ARDS in patients at risk, but also multiorgan dysfunction after the development of ARDS [197]. Body mass index (BMI) [198] exhibits a U-shaped distribution of relative risk for mortality in ARDS, with higher risk falling on both the low and high ends of the curve. In the case of BMI, although it is somewhat intuitive that patients with either an exceedingly low or excessively high BMI would be at greater risk of death, an unexpected finding was that of the lowest risk belonging to those considered “obese,” with a BMI between 30 and 40 [198]. As the science of genomics has advanced, several candidate genes and genetic polymorphisms have been found to be associated with an increased susceptibility to the syndrome and to an increased risk of mortality [199,200]. Although no specific gene or polymorphism has been proven sensitive or specific enough for routine clinical screening, significant work has been done linking ARDS risk to genes affecting immune regulation, epithelial and endothelial function, and oxidative stress [200], and this area of research has increased our understanding of the pathogenesis of ARDS and is providing insight into potential new therapies [41,200].

Outcomes

Estimates of mortality from ARDS once ranged as high as 70% [63,201]. Despite a documented decline between the early 1980s and late 1990s [63,201], mortality from ARDS appears to have now plateaued between 30% and 40% for all patients [9,25]. As mortality has slowly improved for ARDS, there has been growing interest in the longer-reaching consequences of this condition [202,203]. In particular, ARDS survivors
often suffer from an impairment in neurocognitive skills [204,205], and the perception of a poor quality of life [203,206]. By as far as 1 year from recovery, although many recover spirometric lung function, the majority of ARDS survivors have a diminished diffusing capacity and exercise tolerance lasting out to 5 years from discharge [203,207]. One report noted less than half of all ARDS survivors returning to work after 1 year and about three-quarters returning to work within 5 years [207]. Many survivors likewise suffer from depression and anxiety, with depression occurring in one-quarter to one-half of all ARDS survivors as far as 2 years out from recovery [203]. Rates of anxiety-related symptoms have been reported as high as 41%, remaining as high as 24% 1 to 2 years out from discharge [203]. Posttraumatic stress disorder (PTSD) is also a significant concern among ARDS survivors with psychiatrist-diagnosed PTSD rates of 44%, 25%, and 24% reported at discharge, 5, and 8 years later, respectively [208]. Of note, predictors of PTSD symptoms in this setting include higher benzodiazepine usage, and recall of delusional experiences from the ICU stay [203].

A regimented sedation protocol designed to promote daily sedation interruption and reduced total cumulative dosing in critically ill patients is associated with a decreased number of days in the ICU and fewer days on mechanical ventilation [209]. Furthermore, this strategy has been associated with lower rates of PTSD-related symptoms following recovery [210]. The feasibility and importance of establishing clear sedation goals and using validated tools for sedation assessment in critically ill patients have been firmly established, and this standard of care is now a part of established professional society guidelines for sedation in the ICU [211].

Utility of Ultrasonography for Diagnosis and Management of ARDS

A key differential point in the diagnosis of ARDS is whether the patient with bilateral lung infiltrates has primary lung injury, cardiac failure, or, on occasion, both ARDS and CPE. This is an important consideration when managing the patient who fulfills the Berlin criteria for ARDS, but where the question remains as to what extent cardiac failure may contribute to the process. Lung ultrasonography combined with echocardiography has utility in making this distinction.

Equipment Requirements and Scanning Technique

Equipment requirements and scanning technique are described in Chapter 11 Lung Ultrasonography. In addition to the standard phased array probe used for lung ultrasonography, the linear vascular probe has specific application for examination of pleural line morphology. Pleural
line morphology is determined with the high-frequency linear probe, whereas B-line distribution is determined with the low-frequency phased array probe.

**Diagnosis of ARDS**

The characteristic findings of lung ultrasonography in ARDS include B lines and consolidation. The presence of multiple B lines indicates an alveolar interstitial syndrome (AIS) and correlates with an increase in extravascular lung water [212]. This may be caused by permeability failure, as in ARDS, or by elevation of left atrial pressure (LAP) with resulting CPE. The pattern of B-line distribution in ARDS is multifocal in association with irregularity of the visceral pleural surface (see Chapter 11 Lung Ultrasonography). The pattern of B-line distribution in CPE is typically more even, more distributed to the gravitationally dependent lung regions, and associated with a more smooth and regular pleural line (see Chapter 11 Lung Ultrasonography). The demonstration with ultrasonography of a nonhomogeneous AIS pattern with spared areas, pleural line irregularity, and lung consolidations is strongly predictive of ARDS (see Chapter 11 Lung Ultrasonography), whereas the finding of a homogeneous AIS pattern with smooth pleural line and no lung consolidations is strongly predictive of CPE [213].

Lung ultrasonography, chest radiography, and chest CT alone cannot make a diagnosis of ARDS or CPE, because there are other disease processes that can mimic these entities. The results of imaging can only support the diagnosis of ARDS, whereas other elements are required to meet the Berlin definition. Lung ultrasonography gives results that are superior to auscultation and standard radiography for detection of AIS and consolidation but provides utility similar to that of chest CT for the diagnosis of ARDS or CPE [214,215].

Similar to chest radiography and CT imaging, a limitation of lung ultrasonography is in the occasional patient who has both ARDS and CPE, or in the patient who has preexisting lung disease with AIS and pleural irregularity with superimposed acute CPE. Categorization of acute hypoxemic respiratory failure between CPE, ARDS, and miscellaneous causes is aided by combining thoracic ultrasonography with basic echocardiography (see Chapter 16 on Critical Care Echocardiography). The combined findings of an abundance of B lines, the presence of reduced left ventricular function, a left-sided pleural effusion, and a dilated inferior vena cava can help support the diagnosis of CPE [32].
Echocardiography allows a semiquantitative estimate of LAP by application of a standard algorithm [216]. The examination requires training in advanced critical care echocardiography, because it utilizes Doppler measurements that are not part of the basic critical care–focused echocardiography examination. The operator applies an algorithm [217] that allows classification of LAP as normal or elevated, and this is useful for distinguishing ARDS from CPE. The primary measurement of interest is the ratio of the peak velocity of early mitral valve diastolic inflow (E), measured by pulse wave Doppler between the tips of the mitral valve leaflets, to the peak velocity of the early lateral mitral annulus diastolic movement (e’), the latter value obtained by tissue Doppler measurement (Video 163.1). These values are readily obtained in a large proportion of patients and are often useful, but they require advanced skills in tissue Doppler measurement technique, and they may yield an indeterminate result. If this is the case, the algorithm requires using a further series of measurements, the complexity of which precludes their regular use in the ICU [217].

Management of ARDS

The use of PEEP in ARDS results in recruitment of atelectatic and poorly aerated lung, which are detectable with lung ultrasonography. On ultrasound, atelectatic lung appears similar to that of consolidated lung, and poorly aerated lung is characterized by abundant B lines. Using a quantitative lung reaeration score, the application of PEEP in ARDS can result in lung recruitment detected by lung ultrasonography, which can be correlated with recruitment volumes interpolated from changes in the pressure volume curve [218]. The pressure at which lung recruitment is detected with lung ultrasonography correlates with the lower inflection point determined by a low-flow pressure–volume curve technique [219]. Although improvement of aeration pattern is observed during lung recruitment with PEEP, lung ultrasonography is not able to determine whether there is concomitant overdistension of some areas of the lung [218]. The utility of these results in routine practice is not yet well defined, but lung ultrasonography may offer a method of directly observing lung recruitment that is easily repeated at the bedside in serial fashion, making this technique potentially far more practical than serial chest CT imaging.

If lung ultrasonography and echocardiography indicate that CPE is the primary disease process, or that CPE is contributing to the severity of the ARDS, then the management strategy includes treatment directed toward CPE.
CONCLUSIONS

Since its first published description in 1967, our understanding of the pathogenesis and pathophysiology of ARDS has grown appreciably, and ongoing research efforts continue to provide hope for exciting new therapies in the future. Our improved understanding of this condition has already translated into improved outcomes for patients suffering from ARDS, but its still poor prognosis for those acutely afflicted in the hospital and for those fortunate enough to survive [203] has left room for ongoing progress in the management of these patients. Aside from the obvious importance of reducing mortality from this condition, a reduction of nonpulmonary organ failures, duration of mechanical ventilation, and ICU length of stay, as well as improved quality-of-life measures among survivors, all represent reasonable and tangible outcome goals, but researchers still face challenges in how to best measure and represent these outcomes [220]. Fortunately, there is no shortage of talented and passionately dedicated physicians and scientists searching for solutions to all of these yet unsolved issues.

Acute Respiratory Failure in Pregnancy
CHRISTINE CAMPBELL-REARDON • HELEN M. HOLLINGSWORTH

The overall pregnancy-related maternal mortality ratio in the United States during 2006 to 2010 was 16 deaths per 100,000 live births [1]. Acute respiratory failure remains an important cause of maternal and fetal morbidity and mortality with 0.1% to 0.2% of pregnancies complicated by respiratory failure requiring mechanical ventilatory support [2]. Thromboembolism, amniotic fluid embolism (AFE), and venous air embolism together account for approximately 15% of maternal deaths [1].

This chapter focuses on the causes of acute respiratory failure that are increased in frequency during pregnancy, are unique to pregnancy, or present special management requirements during pregnancy. The spectrum of problems associated with eclampsia is discussed in Chapter 53. Management of the acute respiratory distress syndrome (ARDS) caused by sepsis, trauma, or other etiologies unrelated to pregnancy is discussed in Chapter 163. Table 164.1 lists the causes of acute respiratory failure in pregnancy.

NORMAL ALTERATIONS IN CARDIOPULMONARY PHYSIOLOGY DURING PREGNANCY

Pregnancy alters respiratory physiology by causing changes in lung volumes, mechanics of ventilation, and control of respiration. Despite airway mucosal changes of edema and hyperemia, spirometry studies reveal no significant changes in measurements of the forced expiratory volume in 1 second (FEV\textsubscript{1}) during pregnancy, suggesting that airway function is maintained during pregnancy. Changes in lung volume associated with gestation are relatively small: total lung capacity decreases 4% to 6%, functional residual capacity (FRC) decreases approximately 15% to 25%, and residual volume remains constant. Despite the decrease in FRC, early airway closure has not been demonstrated and specific airway conductance remains constant [3,4]. Diffusing capacity is elevated during the first trimester but then declines, despite continued increases in cardiac output and plasma volume.

As gestation progresses, the resting level of the diaphragm rises, but diaphragmatic excursion with tidal breathing increases. An increased tidal volume (25% to 35%) accounts for much of the 20% to 40% increase in minute ventilation and the mild respiratory alkalosis that are characteristic of early-to-middle pregnancy. An increased respiratory rate also contributes to the increased minute ventilation late in pregnancy (Fig. 164.1).
Normal carbon dioxide tension (PaCO₂) during pregnancy is 27 to 34 mm Hg, suggesting chronic mild hyperventilation. The degree of hyperventilation has been found to be in excess of the amount needed to compensate for increased oxygen consumption; in fact, hyperventilation develops early in gestation, before any significant increase in oxygen consumption occurs. This has been attributed to elevation in levels of progesterone, which has known respiratory-stimulating effects. The exact mechanism by which it produces these effects is not known, but it is thought to include an increase in the central chemoreflex drive to breathe and to changes in acid–base balance such that central and plasma hydrogen ion concentration is increased for any given PaCO₂. In addition, pregnancy is associated with increased sensitivity to CO₂ as measured by CO₂ ventilatory response curves, reflecting the new, lower set point in PaCO₂, possibly mediated by estrogen and progesterone. The respiratory alkalosis seen during pregnancy causes a compensatory renal excretion of bicarbonate to maintain an arterial pH between 7.40 and 7.45.
The normal arterial oxygen tension (PaO₂) in pregnant women ranges from 100 to 110 mm Hg. Oxygen consumption increases by 20% to 33% by the third trimester, secondary to both fetal and maternal demands. This increased rate of oxygen consumption and low oxygen reserve secondary to a reduced FRC place pregnant patients at risk for the rapid onset of hypoxia.

Circulatory changes occur during gestation to supply oxygen-rich blood to the placenta and to accommodate the stress of labor and delivery. Cardiac output begins to rise during the first trimester and peaks around the 20th week of gestation at 30% to 45% above resting, nonpregnant levels (Fig. 164.2). Thus, measured cardiac output during gestation that is in the normal range for a nonpregnant patient would represent significant hemodynamic compromise for the pregnant patient and, potentially, decreased oxygen delivery for the fetus. As pregnancy progresses, cardiac output becomes dependent on body position. In the supine position, cardiac output can be reduced by 25% to 30% because of compression of the inferior vena cava by the gravid uterus and a resultant decrease in venous return. Cardiac output is higher when the pregnant woman is in the left lateral decubitus position. Estimates of expected cardiac output during gestation should be revised upward for intercurrent stresses, such as fever, infection, and pain.
The gestation-related increase in cardiac output reflects a combination of increases in heart rate and stroke volume. Heart rate increases progressively throughout gestation, reaching a 20% increase over nonpregnant levels of approximately 15 beats per minute. Stroke volume increases more rapidly at first and then stabilizes. Left ventricular compliance must increase in pregnancy because the increased stroke volume appears to be related more to left ventricular enlargement than to increased emptying. The cardiac silhouette on chest radiography may appear enlarged as a result of mild normal left ventricular enlargement and lateral and upward displacement by the gravid uterus.

Further increases of cardiac output occur during labor; cardiac output increases up to 45% over third-trimester values, and, during uterine contraction, cardiac output transiently increases another 10% to 15% because of increased venous return from the contracting uterus. These “autotransfusions” may reach 500 mL when the uterus contracts after parturition. This effect, however, may be offset by blood loss at the time of delivery. In the first few minutes postpartum, cardiac output may increase as much as 80% over prelabor levels, then decrease to 40% to 50% over prelabor values by 1 hour postpartum, and finally return to nearly prepregnant levels by 1 to 2 weeks postpartum.

On the other hand, afterload may increase sharply during labor contractions because of inhibition of blood flow to the contracting uterine muscle. Because uterine blood flow at term accounts for a significant proportion of the cardiac output, marked increases in afterload can occur during contractions and immediately postpartum. These changes in afterload may be important in patients who are sensitive to afterload, such as patients with underlying cardiac disease.

Systemic vascular resistance is generally reduced during pregnancy because of vasodilatation and the low resistance of the uteroplacental vascular circuit. Possible factors leading to vasodilatation include a reduction in vascular responsiveness to norepinephrine and angiotensin II, increased endothelial prostacyclin production, and increased nitric oxide production. The mean blood pressure remains relatively constant despite increases in cardiac output. Pressures in the right ventricle, pulmonary artery, and pulmonary capillaries are no different from nonpregnant values.

During pregnancy, there is expansion of the extracellular fluid volume, with the plasma fluid volume increasing more than the interstitial volume. Maternal blood volume reaches its peak at 32 weeks and is 25%
to 52% above prepregnancy levels. The erythrocyte mass increases by 20% to 30%. However, the plasma volume increases more than the erythrocyte volume, resulting in the physiologic anemia of pregnancy.

Colloid osmotic pressure measurements during gestation reveal a mean decrease of 5 mm Hg, which reaches a plateau at 26 weeks. This parallels a decrease in serum albumin concentrations from approximately 4.0 to 3.4 g per dL. A further decline in colloid osmotic pressure of roughly 4 mm Hg occurs immediately postpartum, probably as a result of a combination of factors, such as recumbency, crystalloid administration, and blood loss. These changes may be even more marked for patients with pregnancy-induced hypertension. Neither the absolute value of colloid osmotic pressure nor the colloid osmotic pressure–pulmonary capillary wedge pressure gradient is an accurate predictor of pulmonary edema because of the multiplicity of contributing variables. However, these trends of colloid osmotic pressure should be considered when interpreting pulmonary capillary wedge pressures, especially for patients who have received large amounts of crystalloid.
DETERMINANTS OF FETAL OXYGEN DELIVERY

Oxygen delivery to fetal tissues can be affected at many levels: maternal oxygen delivery to the placenta, placental transfer, and fetal oxygen transport from the placenta to fetal tissues. The major determinants of oxygen delivery to the placenta are the oxygen content of uterine artery blood, which is determined by maternal PaO$_2$; hemoglobin concentration and saturation; and uterine artery blood flow, which depends on maternal cardiac output. Thus, a decreased PaO$_2$ can be offset somewhat by increased blood hemoglobin concentration or by increased cardiac output. The combination of maternal hypoxemia and decreased cardiac output likely has a profoundly deleterious effect on fetal oxygenation.

Variations in maternal pH also influence oxygen delivery. Alkalosis causes vasoconstriction of the uterine artery, resulting in decreased fetal oxygen delivery. This effect is magnified by a leftward shift in the maternal oxyhemoglobin saturation curve, which increases oxygen affinity and, consequently, decreases oxygen transfer to the umbilical vein. Although mild maternal acidosis does not enhance uterine blood flow because the uterine vasculature is already maximally dilated, it shifts the maternal oxyhemoglobin saturation curve to the right, leading to decreased oxygen affinity and increased fetal oxygen delivery. Maternal hypotension and increased sympathetic stimulation (exogenous or endogenous) both cause uterine arterial vasoconstriction.

The importance of maternal cardiac output is supported by the observation that women with left ventricular outflow obstruction have an increased incidence of fetal death and surviving infants have an increased incidence of congenital heart disease. Data from a sheep model, however, suggests that a decrease in uterine blood flow up to 50% for brief periods does not appreciably decrease fetal and placental oxygen uptake. Chronically decreased maternal cardiac output may have other effects, perhaps on placental development, that explain the results in women with left ventricular outflow obstruction.

The interaction of maternal and fetal circulations in the placenta most likely follows a concurrent exchange mechanism. This is less efficient than a countercurrent exchange mechanism and partly explains why the PaO$_2$ in the fetal umbilical vein, which carries oxygenated blood to fetus, is in the range of 32 mm Hg, far lower than uterine vein PaO$_2$, and why increased maternal inspired oxygen increases uterine artery oxygen tension but does not cause major increases in umbilical vein PaO$_2$. 
Despite low umbilical vein PaO$_2$, fetal oxygen content is actually quite close to maternal oxygen content because of the shape of the oxyhemoglobin saturation curve for fetal hemoglobin (Fig. 164.3). This is one of the major protective mechanisms for fetal oxygenation. The fetal oxyhemoglobin saturation curve is relatively unaffected by changes in pH; although acidosis may decrease maternal oxygen affinity, fetal oxygen affinity remain unchanged.

![Oxygen dissociation (equilibrium) curves of human fetal and maternal blood.](image)

**FIGURE 164.3** Oxygen dissociation (equilibrium) curves of human fetal and maternal blood. The effect of pH on the position of the curve (Bohr effect) is shown on the inset. The oxygen capacity of 16 mL per 100 mL blood on the right-hand ordinate refers to maternal blood.

Other placental factors that determine fetal oxygenation are the amount of intraplacental shunt, degree of matching of maternal and fetal blood flows, and the presence of any placental abnormalities, such as placental infarcts. There seem to be no placental autoregulatory mechanisms that increase blood flow in response to decreased maternal PaO$_2$.

Mathematical models predicting the optimal apportionment of fetal cardiac output between umbilical (to collect oxygen) and systemic (to
deliver oxygen) circulations have yielded values surprisingly close to those measured under normal physiologic conditions. This appears to be another compensation mechanism for the apparent inefficiency (concurrent exchange mechanism) of the placenta. One disadvantage in terms of oxygen delivery to fetal tissues is that oxygenated umbilical vein blood is mixed in the fetal inferior vena cava with deoxygenated systemic venous blood before delivery to the systemic circulation. Thus, fetal arterial blood has an even lower PaO$_2$ than umbilical vein blood. This is compensated for in part by a high fetal cardiac output relative to oxygen consumption, thus enhancing oxygen delivery to fetal tissues. The fetal circulation appears to have the ability to autoregulate in the face of hypoxemia to protect the brain, adrenal glands, and heart. How long this adaptation can be depended on safely before organ damage occurs is not known.

How well do the compensatory mechanisms that provide adequate oxygen supply to the fetus under normal conditions manage during maternal hypoxia? Calculation of oxygen stores in the term infant with 60% hemoglobin saturation yields a total oxygen content of 40 mL. Given an oxygen consumption of 6 mL/kg/min, or approximately 18 mL per minute at term, this reserve lasts barely 2 minutes when the maternal oxygen supply is completely interrupted. The shape of the fetal oxyhemoglobin dissociation curve places umbilical vein PaO$_2$ values below 30 mm Hg on the steep part of the curve, so small changes in maternal PaO$_2$ may cause significant changes in fetal oxygen content. A maternal PaO$_2$ greater than 70 mm Hg should be maintained to prevent adverse consequences to the fetus. Concern regarding the adequacy of fetal oxygen supply is further reduced if a normal maternal PaO$_2$ of 90 mm Hg or greater is achieved without too great a risk of maternal barotrauma or oxygen toxicity [5].
CAUSES OF ACUTE RESPIRATORY FAILURE

This section describes the more common causes of acute respiratory failure in pregnancy in terms of frequency, clinical presentation, pathophysiology, and diagnosis.

Thromboembolic Disease

Fatal pulmonary embolism (PE) is a rare complication in pregnancy, but it accounts for 9.3% of all pregnancy-related deaths in the United States [1]. Thromboembolic complications have been estimated to occur in 5 to 12 per 10,000 pregnancies [6]. The increased frequency of thromboembolic disease in pregnancy may be attributable to a hypercoagulable state along with venous stasis. During pregnancy, there is a progressive increase in coagulation factors I, II, VII, VIII, IX, and X. There is a decrease in protein S and a progressively increased resistance to activated protein C [7]. The activity of plasminogen activator inhibitor types 1 and 2, which are inhibitors of fibrinolysis, also increases [8]. Venous stasis may occur because of a hormonally induced dilation of capacitance veins and uterine pressure on the inferior vena cava [9]. Factors that further increase the risk of thromboembolic disease during pregnancy and the puerperium include (a) cesarean section, which has a 10 times greater risk of fatal PE than does vaginal delivery; (b) increased maternal age; (c) multiparity; (d) obesity, especially in association with bed rest; (e) personal or family history of thromboembolism; (f) suppression of lactation with estrogen; (g) surgical procedures during pregnancy and early puerperium; and (h) inherited thrombophilias such as deficiencies of protein C or S, the presence of antiphospholipid antibodies, the presence of factor V Leiden, and prothrombin gene mutations [9].

The appropriate diagnostic steps and treatment of venous thrombosis and PE in nonpregnant patients are reviewed in Chapter 92. This chapter focuses on the diagnosis and management of massive PE associated with severe respiratory and hemodynamic compromise during pregnancy. Respiratory failure may ensue in PE when extensive occlusion of the pulmonary vasculature or concomitant pulmonary edema occurs.

Although none of the symptoms, physical signs, or results of laboratory, radiographic, or electrocardiographic studies are specific for PE, these investigations can help rule out other diseases in the
differential diagnosis. The usefulness of the serum D-dimer levels in diagnosing thromboembolic disease in pregnancy is limited because D-dimer levels are increased during normal pregnancy, with levels increasing as gestation progresses and peaking at delivery and in the early postpartum period [10].

The typical hemodynamic findings in nonpregnant patients with massive PE are delineated in Chapter 92. Although there are no data for pregnant patients with massive PE, similar findings would be anticipated because pregnancy does not significantly alter right heart and pulmonary artery pressures. Thus, in a pregnant patient with massive PE, pulmonary artery balloon occlusion pressure (i.e., pulmonary capillary wedge pressure) would be expected to be normal or low, mean pulmonary artery pressure moderately elevated (≥35 mm Hg), and right atrial pressure moderately elevated (>8 mm Hg).

Recent guidelines have been published to aid in the diagnostic evaluation of pregnant patients suspected of having a PE [11]. In pregnant patients with suspected PE, with signs and symptoms of acute deep vein thrombosis (DVT), bilateral compression ultrasonography of the lower extremities should be performed. Further diagnostic evaluation is not required when a DVT is found in the legs, because the treatment for DVT and PE is the same. A negative compressive ultrasound of the lower extremities does not rule out the presence of PE, so further diagnostic investigation is required. In a pregnant patient with suspected PE, with no signs or symptoms of DVT, a chest X-ray should be performed with abdominal shielding. If the chest X-ray is normal, the next diagnostic test recommended is a ventilation–perfusion scan because this exposes the mother’s breasts to less carcinogenic radiation than a computed tomography-pulmonary angiogram (CT-PA). A CT-PA is performed when the clinical suspicion for PE is high and the initial chest X-ray is abnormal or if the ventilation–perfusion scan is nondiagnostic [11]. In the nonpregnant patient population, CT-PA has become the study of choice for PE. Data from The Prospective Investigation of Pulmonary Embolism Diagnosis II Trial (PIOPED II) trail determined the sensitivity and specificity of CT-PA for detecting PE to be 83% and 96%, respectively [12]. Pregnancy was an exclusion criterion in this study, so there is a lack of prospective data assessing the sensitivity and specificity of CT-PAs in pregnancy.

Fetal exposure to radiation during imaging studies can be minimized by abdominal shielding and using brachial access. A CT-PA delivers slightly lower doses of radiation (0.003 to 0.131 mGy) to the fetus compared with ventilation–perfusion scanning (0.32 to 0.74 mGy) [13,14]. However, a CT-PA delivers higher radiation doses (7.3 mGy) to the mother compared with ventilation–perfusion scanning (0.9 mGy) [13–15].
Amniotic Fluid Embolism

AFE is a rare, but usually catastrophic, complication of pregnancy and delivery. The incidence of AFE is approximately 1.9 to 6.1 cases per 100,000 deliveries [16,17]. The mortality rates in patients presenting with the classic signs and symptoms of AFE exceed 60%. If AFE is complicated by cardiac arrest, fewer than 10% of these patients are discharged alive from the hospital [17]. Of the women who survive AFE, only 15% of them are neurologically intact as a result of hypoxic encephalopathy [16].

It is unknown why amniotic fluid enters the maternal circulation of some patients. Registry and cohort studies have been analyzed to determine potential predisposing risk factors for AFE. Suggested risk factors include older maternal age (mean, 32 years), multiparity (88% of cases), amniotomy, cesarean section, abruptio placenta, insertion of intrauterine fetal or pressure monitoring devices, and term pregnancy in the presence of an intrauterine device [16]. However, based upon the clinical evidence at this time, no specific demographic or clinical risk factor has been identified that could be intervened on to reduce the risk of AFE. AFE is considered unpredictable and unpreventable at this time [17].

Amniotic fluid enters the maternal circulation through one of three ports: endocervical veins, uterine tears (small tears may occur in the lower uterine segment as a part of normal labor), and uterine injury secondary to iatrogenic manipulation, such as cesarean section, insertion of monitoring devices, or membrane rupture. The two life-threatening consequences of AFE are cardiopulmonary collapse and disseminated intravascular coagulation (DIC). These may occur simultaneously or in sequence. The pathophysiologic process of cardiopulmonary collapse remains controversial. It is possible that amniotic fluid contains vasoactive substances or fetal antigens that provoke an abnormal hemodynamic and immunologic response in the mother that results in the AFE syndrome [17]. There may be a biphasic response to AFE with initial hypoxemia and acute pulmonary hypertension, followed by left ventricular failure. Elevation of the pulmonary capillary wedge pressure and reduction in cardiac output and left ventricular stroke work index have been documented [17].

Acute left heart failure contributes to the development of pulmonary edema, which leads to dyspnea, tachypnea, and cyanosis. Other factors potentially contributing to pulmonary edema include cardiodepressive humoral factors from the amniotic fluid, vigorous fluid resuscitation, increased permeability pulmonary edema, and hypoxia causing myocardial ischemia [18].

The other major consequence of AFE is coagulation failure. In 10% to 15% of patients, excessive bleeding, particularly uterine bleeding, may be
the first sign of AFE. In all, 30% to 45% of women surviving the first 30 to 60 minutes of AFE will have clinical evidence of coagulopathy with severe bleeding. Bleeding from DIC may be seen within the first 10 to 30 minutes following AFE [18]. The factors that initiate DIC are not known.

The abrupt onset of severe dyspnea, tachypnea, and cyanosis during labor or the early puerperium is the classic presentation of AFE, characterizing more than one-half of cases. Shock, which is out of proportion to blood loss, is the first manifestation in another 10% to 15%. Seizure activity may be the presenting sign in 30% of cases. In addition, fetal bradycardia is seen in 17% of US registry cases. Bleeding is the forerunning sign in 10% to 15% of patients, and the longer the survival, the greater the likelihood that the patient will manifest respiratory failure, cardiovascular collapse, and DIC. Whatever the presenting symptom complex, 90% of cases occur before or during labor [18]. Other complications, such as acute renal failure and signs of central nervous system injury, are probably secondary to hypotension and hypoxemia. Prodromal symptoms, such as vomiting and shivering, are nonspecific and frequently associated with otherwise uneventful deliveries.

Diagnostic criteria for AFE previously rested on demonstration of fetal elements such as epithelial squamous cells from fetal skin, lanugo hairs, fat from the vernix caseosa, mucin from fetal gut, and bile-containing meconium in the maternal circulation. These elements are not pathognomonic for AFE, because these amniotic fluid components are found in the maternal circulation of healthy pregnant women without AFE [17]. Therefore, the antemortem diagnosis of AFE still rests predominantly on the clinical setting and the exclusion of other causes of acute respiratory failure. The role of echocardiography in the diagnosis of AFE is not yet known. Cardiac echo may show decreased left ventricular function or echodense material in the right atrium or right ventricular outflow tract [17]. Diagnostic biomarker assays are not currently available for clinical diagnosis of AFE.

Fetal outcome is also poor for AFE. The perinatal mortality from national registries ranges from 7% to 38%, with up to 50% of the surviving children experiencing permanent neurologic injury [18].

**Venous Air Embolism**

Venous air embolism is the entrainment of air into the venous system where it then travels to the right ventricle and the pulmonary circulation. Venous air embolism has been described during normal labor, delivery of
patients with placenta previa, criminal abortions using air, and
insufflation of the vagina during gynecologic procedures. Cases have also
been reported of venous embolism occurring following orogenital sex
[19]. Venous air embolism may account for as many as 1% of maternal
deaths [1]. Presumably, the subplacental venous sinuses are the sites of
air entry when antepartum or peripartum air embolism occurs.

The clinical presentation of venous air embolism varies according to
the volume and speed of air entrainment into the vascular circulation.
Venous air embolism can affect the cardiac, respiratory, and neurologic
systems. Sudden, profound hypotension is the most common presenting
sign of venous air embolism. Cough, dyspnea, dizziness, tachypnea,
tachycardia, and diaphoresis may also be noted. Hypotension is usually
followed quickly by respiratory arrest. The classic sign associated with air
embolism is the mill wheel murmur, which is audible over the
precordium [19]; a drum-like or bubbling sound may also be heard.
Electrocardiographic evidence of ischemia, right heart strain, and
rhythmias have been described, and metabolic acidosis, presumably
carried by lactic acid production, may be present [19] (see Chapter 198).

Neurologic symptoms develop as a consequence of cerebral
hypoperfusion from cardiovascular collapse and from paradoxical
embolization if a patent foramen ovale is present [19]. Transesophageal
echocardiography (TEE) and transthoracic echocardiography have been
utilized to identify air embolism, the route of the embolism, and the
severity of the air embolism [19]. TEE is the most sensitive monitoring
technique and is able to detect 0.02 mL per kg of air or bubbles
measuring 5 to 10 microns [19]. Based on data from surgical procedures,
precordial Doppler ultrasound can be used for surveillance of air
embolism by detection of alterations in the ultrasonic pattern caused by
the embolism and is able to detect as little as 0.05 mL per kg of air [20].
End-tidal carbon dioxide demonstrates a sudden increase in the level of
end-tidal CO₂ during a venous air embolism event [19].

The volume of air that is likely to be lethal seems to vary with the rate
of infusion and patient position. A bolus of 200 to 300 mL of air or 3 to 5
mL per kg has been reported to be the lethal dose in humans [19,20]. The
mechanism by which air embolism leads to noncardiogenic pulmonary
edema is not known. It is thought that entrapment of air bubbles in the
pulmonary circulation leads to activation of complement, neutrophils,
and platelets, resulting in mediator release, protease activation, oxidant
stress, and endothelial injury [19]. This inflammatory response then
precipitates noncardiogenic pulmonary edema [19].

Aspiration of Gastric Contents

Aspiration of acidic gastric contents into the tracheobronchial tree was
first described in 1946 by Mendelson [21] in women during labor and delivery. Maternal deaths from pulmonary aspiration have been steadily declining as a result of changing anesthesia practices, including a shift to regional anesthesia from general anesthesia for delivery [22].

At term, several factors contribute to an increased risk of aspiration of stomach contents: (a) increased intragastric pressure caused by external compression by the gravid uterus, (b) progesterone-induced relaxation of the lower esophageal sphincter, (c) delayed gastric emptying during labor, (d) supine position, and (e) analgesia-induced decreased mental status and decreased vocal cord closure [23]. The pulmonary pathophysiologic consequences of gastric aspiration are a consequence of the acidity and the particulate content of the gastric contents and the risk of bacterial superinfection. Acid aspiration causes a direct injury to the airway resulting in desquamation and loss of ciliated and nonciliated cells, including the alveolar type II cells. An inflammatory response is also triggered by the acid aspiration, leading to an increase in alveolar permeability with a loss in lung compliance and a decrease in ventilation–perfusion matching [23]. Inhaled particulate matter may cause acute airway obstruction and immediate death.

The volume of acid aspiration determines, in part, the rapidity of symptom onset. Aspiration of smaller volumes may go unnoticed clinically until 6 to 8 hours later, when tachypnea, tachycardia, hypoxemia, hypotension, bronchospasm, and production of frothy, pink sputum are noted in association with diffuse opacities on chest radiography. Progression of chest radiographic findings may continue for up to 36 hours. The clinical course may follow one of three patterns: (a) rapid improvement during 4 to 5 days, (b) initial improvement followed by deterioration caused by supervening bacterial pneumonia, and (c) early death as a result of intractable hypoxia [23]. Predictors of poor outcome include low pH, large volume, and a greater amount of particulate content of the aspirate. The bacterial pathogens in this setting are usually oropharyngeal anaerobes, although the longer the patient is in the hospital before clinical development of pneumonia, the greater the likelihood of facultative, Gram-negative bacillary, and Staphylococcus aureus infections [23].

Respiratory Infections

The prevalence of pneumonia during pregnancy ranges from 0.78 to 2.7 cases per 1,000 deliveries. The maternal mortality rate from pneumonia has decreased from 20% to 3% since the advent of antibiotics [24]. The major factors in improving fetal and maternal outcome seem to have been earlier presentation and prompt institution of antibiotic therapy. Although pneumonia rarely progresses to respiratory failure, it is
advisable to assess maternal oxygenation in all cases of maternal pneumonia. The spectrum of organisms to consider is similar to that in the nonpregnant population; the most common organisms are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Mycoplasma pneumoniae*. *Legionella* pneumonia accounts for up to 22% of community-acquired pneumonia [25].

---

Certain other respiratory infections (e.g., influenza, varicella, coccidioidomycosis, tuberculosis [TB], listeriosis, and severe acute respiratory syndrome [SARS]) have been associated with increased maternal and fetal morbidity and mortality. These particular infections can be virulent in the pregnant patient because of alterations in the immune status. Specifically, during pregnancy, there is a decreased lymphocyte proliferative response, a decrease in the natural killer cell activity, and a decrease in the number of helper T4 cells [24]. Fortunately, the impairment in maternal immune response is mild, and the increase in maternal morbidity is small.

In the influenza pandemics of 1918, 1957, and 2009, an excess incidence of influenza pneumonia was noted among pregnant women. A 50% incidence of influenza pneumonia and an overall mortality of 27% for influenza in pregnancy were found in 1918 [26]. In the 1957 pandemic, several studies noted that 50% of deaths from influenza in women of childbearing age were in pregnant patients [26]. Autopsy reports noted that the cause of death in pregnant women was respiratory insufficiency caused by fulminant influenza pneumonia, rather than secondary bacterial infection, the more common cause of death in nonpregnant influenza patients. The pandemic in 2009 was attributed to influenza A(H1N1)pdm09 virus, and the Centers for Disease Control and Prevention data from 2009 to 2010 revealed that 12% of pregnancy-related deaths were attributed to influenza A(H1N1)pdm09 [27]. In addition, higher rates of miscarriage, preterm birth, and small for gestational age babies have been noted in mothers infected with influenza [26]. The typical symptoms of influenza include cough, fever, sore pharyngitis, rhinorrhea, diarrhea, headache, and myalgias [26].

The incidence of varicella infection during pregnancy is 1 to 5 cases per 10,000 pregnancies. The introduction of the varicella vaccine in 1995 has led to this lower incidence because of high rates of varicella-zoster virus seropositivity among adults in the United States [28]. Varicella pneumonia is estimated to complicate 10% to 20% of maternal infections, although a study of a large database cohort found the incidence of maternal varicella pneumonia to be 2.5% with no maternal deaths [28].
In this study, 13% of the patients required ventilatory support compared with 40% historically [28]. Furthermore, the mortality rate for maternal varicella pneumonia has declined significantly since the development of antiviral therapy and institution of varicella vaccination. Historically, the mortality rate for maternal varicella pneumonia was 41%, but, in the era of antiviral therapy and vaccination, the mortality rate is now estimated to be 3% to 14% [28]. Cigarette smoking appears to be an important risk factor in the progression of varicella into pneumonia [24].

Respiratory symptoms usually develop 2 days after the onset of fever, rash, and malaise. Typical symptoms are cough, dyspnea, hemoptysis, and chest pain [24]. Generalized varicella-zoster infections may also be associated with hepatitis, myocarditis, nephritis, thrombocytopenia, and adrenal hemorrhage [24]. Varicella during pregnancy can lead to intrauterine infection, which can result in prematurity, spontaneous abortion, and stillbirth [24]. In the absence of dissemination, herpes zoster does not appear to be associated with significant maternal morbidity or evidence of fetal infection [28].

SARS is an atypical pneumonia first described in 2002 that is caused by a coronavirus [24]. Symptoms of fever, chills, rigors, headache, malaise, and myalgias develop 2 to 7 days after exposure. A nonproductive cough or dyspnea may develop over 3 to 7 days. This may progress to hypoxemia and respiratory failure. The chest radiograph may show bilateral patchy interstitial opacities. The overall mortality rate for SARS is 3% [29]. One review of 12 cases of SARS during pregnancy demonstrated that 33% of pregnant women required mechanical ventilation, and the maternal mortality rate was 25% [24]. Pregnant patients with suspected or probable SARS should be placed on airborne precautions in a negative pressure isolation room [24].

Maternal Coccidioidomycosis immitis infections are rare, with less than 1 case in every 1,000 pregnancies. Historically, Coccidioidomycosis infection during pregnancy has been reported as having a 20.0% dissemination rate, compared with 0.2% in nonpregnant patients; infections contracted in the second or third trimester have a higher rate of dissemination [30]. Maternal mortality and fetal loss are preventable with appropriate treatment [30]. Case reports of cryptococcosis, blastomycosis, and sporotrichosis in pregnancy are rare enough to suggest that there may be no increased susceptibility to these infections [30].

Disseminated coccidioidal infection should be suspected in patients with primary or chronic progressive coccidioidal pneumonia in whom rapidly progressive respiratory failure and a clinical picture resembling miliary TB develop. Diagnosis is sometimes difficult because sputum is positive in less than 40% of cases, and complement fixation titers may be low [30]. Evaluation of these patients should include a careful search for
extrapulmonary disease (e.g., lumbar puncture, urinalysis, culture of skin lesions) [30]. Peripheral blood eosinophilia is reported in 25% and may be a clue to the diagnosis.

Respiratory failure as a result of infection with *Mycobacterium tuberculosis* is rare. The prevalence of active TB in pregnant women living in low burden countries ranges from 0.06% to 0.25%. In high burden countries, the prevalence of active TB varies depending upon HIV status. In HIV-negative women, the incidence is 0.07% to 0.5% compared with 0.7% to 11% among women who are HIV positive [31]. Pregnancy does not alter the pathogenesis of tuberculous infection or increase the likelihood of latent TB infection progressing to active disease, although pregnant women who are HIV positive and have latent TB infection are more likely to progress to active TB disease [31]. Pregnancy does not alter the response to tuberculin skin testing, so all pregnant women from populations recommended for screening should have a skin or an interferon-γ release test performed if one has not been done previously [32].

In the United States, 24% of the HIV/AIDS cases occur in women [33]. Because the number of women infected with HIV grows, the spectrum of respiratory disease in pregnancy will include an increasing proportion of opportunistic infections and other respiratory complications related to AIDS. *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) pneumonia (PCP) is the most common cause of AIDS-related death in pregnant patients [24]. In a series of 22 patients with PCP in pregnancy, the rate of mechanical ventilation was 59% and the maternal mortality rate was 50%, compared with a mortality rate of 1% to 16% in nonpregnant patients [24]. Diagnostic evaluation follows the same protocol as in a nonpregnant patient with suspected PCP. Induced sputum should be examined for the presence of *P. jiroveci*; if this is negative, flexible bronchoscopy with bronchoalveolar lavage should be performed.

*Listeria monocytogenes*, a cause of meningitis and sepsis in immunocompromised hosts, also has a predilection for pregnant women, most commonly resulting in abortion or neonatal sepsis [34]. The incidence of *Listeria* infection among pregnant women is estimated at 3 per 100,000 compared with 0.29 per 100,000 in the general population [35]. The usual sporadic incidence is 1 to 3 cases for every 1 million of the population each year, but local outbreaks may occur as a result of ingestion of contaminated cheese, cabbage, or milk [35]. Diagnosis may be problematic because of difficulties with isolating the organism from respiratory tract secretions. When *L. monocytogenes* sepsis is suspected, cultures should be obtained from the blood, sputum, rectum, cervix, and amniotic fluid (at the time of delivery) [34]. Patients who develop sepsis or meningitis have been reported to have a case fatality rate of 20% to 30% [34].
Asthma

Asthma affects between 3.7% and 8.4% of pregnant women in the United States [36]. The scope of this section is limited to asthmatic exacerbations during pregnancy that lead to respiratory failure. Studies have shown that poor asthma control during pregnancy is associated with adverse fetal and maternal outcomes. Pregnant women with frequent or severe asthma attacks are more likely to have fetal complications, including growth retardation, preterm birth, low birth weight, neonatal hypoxia, and perinatal mortality. The maternal complications include preeclampsia, gestational hypertension, vaginal hemorrhage, hyperemesis, and complicated labor [36,37]. Women whose asthma is actively managed during pregnancy have no significant differences in maternal and fetal outcomes compared with those of healthy, nonasthmatic women [38,39].

The initial clinical assessment of a pregnant woman with asthma should include personal history (detailing etiologic factors and prior therapy), physical examination, and either peak expiratory flow rate or spirometric pulmonary function testing (see Chapter 172). Peak expiratory flow rates and spirometry do not change with pregnancy and advancing gestation. Therefore, peak expiratory flow rate and spirometry can be used as diagnostic and monitoring tools in the care of pregnant asthmatic women [36]. Although asthma may be the most common cause of airway obstruction during pregnancy, wheezing, shortness of breath, coughing, and sensation of chest tightness are nonspecific, and several other entities may mimic asthma (see Chapter 172).

Assuming the diagnosis of asthma is secure, certain findings taken together can be used to predict which patients are likely to require intensive care unit (ICU) admission. These include diaphoresis, use of accessory muscles, assumption of upright posture, altered level of consciousness, pulse rate greater than 120 beats per minute, respiratory rate greater than 30 breaths per minute, pulsus paradoxus greater than 18 mm Hg, peak expiratory flow rate less than 120 L per minute, or failure of the FEV₁ to increase at least 10% after inhaled bronchodilator therapy [40]. Peak flows have been used for the evaluation of nonpregnant patients with asthma to predict the need for arterial blood gas determination. Flows greater than 200 L per minute (50% of predicted) are virtually never associated with significant hypoxemia or hypercapnia (see Chapter 172). However, because alveolar–arterial oxygen tension gradients are known to be widened in pregnancy [3], it seems prudent to obtain arterial blood gas measurements in pregnant women with asthma who do not show a significant improvement (>20%)
in peak expiratory flow rate after an initial inhaled bronchodilator treatment. Continuous oxygen saturation monitoring is also appropriate.

During acute asthma attacks, arterial blood gas measurements typically reveal mild hypocapnia (PaCO₂ of 35 mm Hg) and moderate hypoxemia. During pregnancy, as noted previously, the baseline PaCO₂ is usually already depressed [3] and probably decreases further with an acute asthma attack. The importance of this is twofold: (a) a PaCO₂ of 35 mm Hg during an acute attack may actually represent “pseudonormalization” caused by fatigue, inability to meet the increased work of breathing, and impending respiratory failure and (b) persistent hypocapnia with associated respiratory alkalosis (pH greater than 7.48) may result in uterine artery vasoconstriction and decreased fetal perfusion [5].

β-Adrenergic Tocolytic Therapy

Tocolytic therapy is administered to delay preterm delivery up to 48 hours so that systemic glucocorticoids can be given to optimize lung maturity with the aim of reducing neonatal morbidity and mortality. Many classes of medications are given for this purpose, including β-agonists, prostaglandin inhibitors, calcium channel blockers, magnesium sulfate, and oxytocin receptor blockers. These agents prevent preterm labor by inhibiting myometrial contractions [16]. The use of relatively β₂-selective agents, such as ritodrine and terbutaline, has diminished the frequency of unacceptable maternal tachycardia, but maternal pulmonary edema has remained a serious side effect. Pulmonary edema associated with tocolytic therapy appears to be unique to pregnancy because it has not been reported when these medications are used to treat asthma. Calcium channel blockers such as nifedipine and nicardipine have also been reported to cause pulmonary edema [41,42].

The typical symptoms and signs of β-adrenergic tocolytic-induced pulmonary edema are chest discomfort, dyspnea, tachypnea (24 to 40 breaths per minute), crackles, and pulmonary edema on chest radiography. Evidence of pulmonary edema develops relatively acutely, occasionally after only 24 hours but usually after 48 hours of β-adrenergic tocolytic therapy. A nonproductive cough is occasionally present. Wheezes, in addition to crackles, were noted in one case [43]. The size of the heart has been difficult to assess on radiographs because of the normal increase in cardiac diameter with pregnancy. The relatively rapid improvement that occurs with discontinuation of β-adrenergic tocolytic therapy (usually in less than 24 hours), the absence of hypotension and clotting abnormalities, and the lack of need for mechanical ventilation support the possibility that these cases represent a separate syndrome related to β-adrenergic tocolytic therapy.
The pathophysiologic mechanisms leading to the development of tocolytic-induced pulmonary edema are not well defined. Fluid overload is an important factor contributing to the pathogenesis. Augmented aldosterone secretion secondary to pregnancy and β-agonist stimulation causes salt and water retention. Tocolytic agents also stimulate antidiuretic hormone secretion, which increases water retention [43]. There are no compelling data to support the hypothesis of cardiac failure as the etiology of tocolytic-induced pulmonary edema. Echocardiography and hemodynamic assessment of affected patients have not revealed cardiac dysfunction [43]. The rapidity of improvement after diuresis is consistent with pulmonary edema caused by increased hydrostatic pressure, rather than an increase in capillary permeability [16].

Pneumomediastinum and Pneumothorax

Pneumomediastinum is another rare complication of pregnancy. Estimates of incidence range from 1 in 2,000 to 1 in 100,000 patients [44]. It occurs most commonly in the second stage of labor and is associated with chest or shoulder pain that radiates to the neck and arms, mild dyspnea, and subcutaneous emphysema of face and neck. Prolonged, dysfunctional labor, coughing, and severe emesis seem to be the predisposing factors. Air from ruptured alveoli tracks centrally along the perivascular sheath into the mediastinum and along fascial planes into the subcutaneous tissues. Very rarely, pneumomediastinum will cause cardiovascular collapse and require surgical decompression [44].

Spontaneous pneumothorax with tension may occur with or without associated pneumomediastinum. It occurs rarely during pregnancy with an incidence estimated at 1 per 10,000 deliveries, but it should be considered in the differential diagnosis of respiratory failure during pregnancy [45]. Risk factors for pneumothorax include asthma, cigarette smoking, crack cocaine use, and history of pneumothorax. Pneumothoraces usually occur during labor or in the immediate postpartum period. The occurrence of pneumothorax may be caused by rupture of subpleural blebs by the changes in intrapleural pressure caused by Valsalva maneuvers during labor [45]. Symptoms of pneumothorax include sudden pleuritic chest pain, dyspnea, and cough. Hypotension may develop if a tension pneumothorax develops. The clinical significance of pneumothorax during pregnancy relates to impaired ventilation and hypoxemia, which can lead to fetal hypoxemia.

Acute Respiratory Distress Syndrome
ARDS is a type of respiratory failure caused by an inflammatory injury to the alveolar–capillary interface that leads to alveolar edema and resultant hypoxemia. The diagnosis of ARDS in pregnant patients is the same for nonobstetric patients. The Berlin definition of acute respiratory distress syndrome (ARDS) states (a) onset of symptoms within 1 week of a known clinical insult or new or worsening respiratory symptoms, (b) chest imaging demonstrating bilateral opacities not fully explained by effusions, lobar/lung collapse, or nodules, (c) respiratory failure not fully explained by cardiac failure or fluid overload, and (d) oxygenation impairment while on positive end-expiratory pressure (PEEP) of 5 cm H₂O. The PaO₂ to FiO₂ ratio can be used to categorize the severity of ARDS. Mild ARDS is associated with PaO₂ to FiO₂ ratio of 201 to 299 mm Hg; moderate ARDS is present if the PaO₂ to FiO₂ ratio is 100 to 200 mm Hg; and severe ARDS is present if the PaO₂ to FiO₂ ratio is ≤100 mm Hg [46]. The pathogenesis of ARDS during pregnancy includes the same etiologies seen in the general population, such as sepsis, aspiration, pancreatitis, trauma, inhalational injury, drowning, and pneumonia. Unique entities of pregnancy that may lead to ARDS include AFE, eclampsia, HELLP syndrome, chorioamnionitis, and endometritis [6].

Published case series report maternal mortality rates between 23% and 39%, with multisystem organ failure as the most common cause of death [47]. Neonatal outcomes are not well studied, but the high rates of fetal death (23%) and spontaneous preterm labor have been reported. [4].
DIAGNOSTIC TESTING

Radiology

Evaluation of patients with respiratory failure usually requires at least one, if not sequential, chest radiograph. Potential adverse fetal effects include congenital malformation, intrauterine growth retardation, and increased risk of leukemia and other malignancies [13,14]. There is no evidence that there is an increased fetal risk of anomalies, growth retardation, or intellectual disability from radiation doses less than 0.05 Gy [13,14]. There may be a small increased risk of childhood leukemia, 1 in every 2,000 compared with a background rate of 1 in every 3,000 [13,14].

The National Council on Radiation Protection Handbook 54 established 5 rad (0.05 Gy or 5 cGy) as the embryonic exposure level not to exceed [14]. The estimated radiation exposures of selected procedures used in the evaluation of pregnant patients with respiratory failure are shown in Table 164.2 [13]. Portable chest radiographs performed daily for 2 weeks to assess location of endotracheal tubes and central venous catheters, as well as response of the underlying illness to treatment, would expose the fetus to approximately 7 mrad (0.07 Gy). A pregnant woman being evaluated for thromboembolic disease with a chest radiograph, ventilation–perfusion scan, and chest CT-PA would have a fetal exposure of less than 500 mrad (0.005 Gy or 0.5 cGy) [11].

Magnetic resonance imaging (MRI) and ultrasonography are not known to be associated with adverse fetal outcomes [48]. The American College of Radiology has published guidelines in which MRI may be considered as a nonionizing imaging study during any trimester if the risk–benefit ratio to the mother is favorable [48]. Gadolinium crosses the placenta to the fetus, so the use of gadolinium-based contrast is not recommended unless the potential benefit to the mother outweighs the potential risk to the fetus [48].

Hemodynamic Monitoring

All pregnant women determined to be critically ill with respiratory failure require cardiopulmonary monitoring, including continuous monitoring of the patient’s heart rate, cardiac rhythm, oxygen saturation, and respiratory rate. The blood pressure and temperature are also evaluated frequently. Pregnant women should also have fetal heart rate and uterine monitoring performed. The frequency of fetal monitoring is determined in consultation with the maternal–fetal medicine team and is dependent upon the gestational age of the fetus and the clinical status of the mother.

The potential indications for invasive hemodynamic monitoring with a pulmonary artery catheterization for obstetric patients include the diagnosis or management of septic shock, classes III and IV cardiac patients in labor, severe preeclampsia or eclampsia during labor, pulmonary hypertension, and severe ARDS. There are no reports of specific complications of pulmonary artery catheterization pertaining to obstetric patients, who are at equal risk as nonobstetric patients for complications such as hematoma or pneumothorax at the time of insertion, balloon rupture, catheter knotting, pulmonary infarct, pulmonary artery rupture, thrombosis, embolism, arrhythmias, right bundle-branch block, valvular damage, and infection (see Chapter 19).

In addition to increases of heart rate and cardiac output, several other changes occur in maternal hemodynamics during pregnancy, labor, and delivery [49]. Pulmonary artery catheterization of 10 healthy pregnant patients was done at term and repeated during the nonpregnant state to determine the hemodynamic changes of normal pregnancy. Significant decreases were noted in the systemic and pulmonary vascular resistances, colloid oncotic pressure, and the gradient between colloid oncotic pressure and pulmonary balloon occlusion pressure in the late third trimester. There was no significant change in central venous pressure, pulmonary balloon occlusion pressure, mean arterial pressure, or left ventricular stroke work index [49].
Because of the complications that may accompany pulmonary artery catheterization, the expense of the procedure, and the lack of formal demonstration of improved morbidity or mortality related to the technique, it has been suggested that caution be exercised when choosing to proceed with pulmonary artery catheterization [50]. Clinical assessment may be inadequate for obstetric patients to differentiate between cardiogenic and noncardiogenic pulmonary edema. Both increased permeability pulmonary edema and pulmonary edema caused by volume overload are common causes of respiratory failure in pregnancy. In addition, careful hemodynamic management is needed to maintain adequate uterine blood flow in compromised patients. Maintaining a good risk to benefit ratio depends on obtaining accurate information, interpreting this information in the context of the stage of pregnancy or labor, and determining the specific situations in which the information will contribute significantly to patient management.

Noninvasive hemodynamic monitoring techniques such as Doppler echocardiography, esophageal Doppler monitoring, thoracic electrical bioimpedance, arterial pressure waveform algorithms, pulse pressure variation, and stroke volume variation require further study in critically ill obstetric patients. Transthoracic echocardiography may assist in the differentiation of life-threatening hypotension of the critically ill pregnant patient. Cardiac echo is able to identify pericardial tamponade, right-sided heart failure or left-sided heart failure, intracardiac air, and enables the clinician to direct therapy appropriately [51].

Fetal Monitoring

Methods to assess antepartum fetal well-being include maternal assessment of fetal activity, cardiotocography, contraction stress testing, calculation of a biophysical profile, fetal Doppler ultrasound, and assessment of fetal lung maturity. When respiratory failure occurs early in gestation, before fetal viability is ensured, and when early delivery is not an option, the best course is to focus on optimizing care for the mother and not on minute-to-minute variations in fetal heart rate. However, it is reasonable to measure and record a daily fetal heart rate to document that the fetus is alive. When she is able, the mother can report whether fetal movement is present. Continuous external fetal heart rate monitoring via cardiotocography may be helpful during surgical procedures to alert the anesthesiologist to problems with maternal ventilation or cardiac output. If respiratory failure persists for several weeks, fetal growth measurement by ultrasound may be indicated. When
gestation has progressed enough for delivery by cesarean section, amniocentesis may be helpful to determine fetal lung maturity [52].
TREATMENT

Supportive Therapy

Mechanical ventilation, nutritional support, and maintaining an adequate blood pressure are important considerations in respiratory insufficiency during pregnancy.

Mechanical Ventilation

The guidelines for intubation and mechanical ventilation are essentially the same for pregnant patients as for nonpregnant patients: (a) inability to maintain an adequate PaO$_2$ with supplemental oxygen, (b) uncompensated respiratory acidosis, and (c) inability to clear secretions or need to protect the airway because of altered mental status (see Chapters 8, 166, and 167). For nonpregnant patients, an adequate PaO$_2$ is considered to be 60 to 65 mm Hg, but, in pregnancy, a goal PaO$_2$ of 70 mm Hg or greater is preferred to provide better oxygenation for the fetus.

Pregnancy is associated with alterations in physiology that may make airway management more difficult compared with that of nonpregnant patients. Elevated estrogen levels and an increase in blood volume during pregnancy may contribute to mucosal edema [3]. Smaller endotracheal tubes sized 6 to 7 mm may be required to minimize the risk of upper airway trauma during intubation. The decreased FRC in pregnancy may lower the oxygen reserve such that, at the time of intubation, a short period of apnea may be associated with a precipitous decrease in PaO$_2$ [3]. Therefore, before any attempt at endotracheal intubation, 100% oxygen should be administered, either by mask when the patient is able to ventilate spontaneously or by hand resuscitation bag when the patient requires assisted ventilation. However, hyperventilation to increase the PaO$_2$ before intubation should be avoided because the associated respiratory alkalosis may actually decrease uterine blood flow. Multiple factors place a pregnant patient at an increase risk of aspiration during intubation. These include incompetence of the gastroesophageal junction caused by the position of the gravid uterus, delayed gastric emptying during labor, progesterone-mediated smooth muscle relaxation of the gastrointestinal mucosa, and decreased lower esophageal sphincter tone [3].

Initiating mechanical ventilation follows the same general principles for pregnant patients as for nonpregnant patients, although the goals of arterial blood gas are different in the pregnant patient. In general, the
minute ventilation should be adjusted to aim for a PaCO$_2$ of 30 to 32 mm Hg, the normal level in pregnancy; marked respiratory alkalosis should be avoided because of the resultant decrease in uterine blood flow. Maternal permissive hypercapnia may also be deleterious to the fetus because of resultant fetal respiratory acidosis. The transfer of carbon dioxide across the placenta depends on the difference of 10 mm Hg between the fetal and maternal umbilical veins. Plateau pressure, which reflects transalveolar pressure, should be kept under 30 cm H$_2$O to minimize the risk of barotrauma. Adequate fetal oxygenation requires a maternal PaO$_2$ of 70 mm Hg or more which corresponds to an oxygen saturation of 95% [3].

Mechanical ventilation of a pregnant patient with ARDS should follow the guidelines of the ARDS Network Study using nonpregnant predicted body weight [53]. This study has shown the efficacy of delivering tidal volumes is based on ideal body weight. This strategy avoids overdistention of the lung and maintains a plateau pressure less than 30 cm H$_2$O. The initial setting for tidal volume is 6 to 8 mL per kg of ideal body weight. The respiratory rate is adjusted to maintain a maternal PaCO$_2$ between 28 and 32 mm Hg while monitoring for the development of intrinsic PEEP or dynamic hyperinflation. If the pregnant patient continues to have a respiratory acidosis despite a high respiratory rate, the tidal volume may be increased as long as the plateau pressure remains less than 30 cm H$_2$O. For most patients with ARDS, PEEP is initiated at 5 cm H$_2$O and adjusted upward depending on the required fraction of inspired oxygen (see Chapters 163 and 166). As in nonpregnant patients, the goals are to reduce the maternal inspired oxygen concentration to less than 50%, if possible, and to maintain adequate oxygen delivery without compromising cardiac output or risking further lung damage caused by excess intra-alveolar pressure. Strict monitoring of fluid status is necessary because the hypervolemia of pregnancy may contribute to the progression of respiratory failure.

Alternative ventilation strategies for patients failing conventional ventilation modes in ARDS have not been studied during pregnancy. The routine use of airway pressure-release ventilation, high-frequency oscillatory ventilation, lung recruitment maneuvers, prone positioning, and inhaled vasodilators during pregnancy need further study before they can be recommended. There have been several reports utilizing extracorporeal membrane oxygenation in pregnant patients with H1N1 influenza with severe refractory ARDS. The maternal and fetal mortality rates were reported to be 28% [54].
For patients with asthma, respiratory rate and tidal volume should be no greater than necessary to maintain oxygenation. Lower respiratory rates and tidal volumes help reduce airway pressures, thereby reducing volutrauma and barotrauma [53]. Inspiratory flow rates can be increased to allow adequate time for expiration. Increasing the inspiratory flow rate during volume-cycled mechanical ventilation decreases the inspiratory to expiratory ratio and mitigates air trapping (for further discussion of mechanical ventilatory support of the patient with asthma, see Chapters 166 and 172). Permissive hypercapnia is often necessary in patients with severe asthma to prevent volutrauma and hemodynamic compromise. There have been no reported cases of controlled hypoventilation during pregnancy, and the potential risk of fetal respiratory acidosis must be considered before instituting this therapy.

Lowering oxygen consumption by treating fever and suppressing spontaneous respiration is also helpful. The recommendations for sedation, analgesia, and muscle paralysis for pregnant women on mechanical ventilation are the same as those for all critically ill patients. Patients requiring sedation while on mechanical ventilation are managed using an assessment tool for agitation and sedation, with titration of sedation so that the patient is comfortable but easily aroused and able to follow simple commands. Patients are also assessed for delirium and pain while they are on mechanical ventilation. It is recommended that sedation be interrupted daily and coupled with a spontaneous breathing trial. Guidelines also recommended the use of analgesic medication as first-line therapy for patients requiring mechanical ventilation. Sedatives are then added only if management of analgesia is ineffective. Compliance with sedation monitoring, daily interruption of sedation, and a daily attempt at spontaneous breathing have resulted in fewer days on the ventilator and fewer days in the ICU [55]. Narcotics that may be used in pregnancy include morphine, fentanyl, and hydromorphone. Morphine is typically avoided in renal failure because of accumulation of active metabolites. These medications are not teratogenic, and appear to be without fetal effects except when used at the time of delivery or when used excessively, as in narcotic addiction [55]. The use of nonbenzodiazepines, rather than benzodiazepines, for patients requiring mechanical ventilation results in fewer days on mechanical ventilation, less delirium, and fewer days in the ICU. If a sedative is required for a mechanically ventilated patient, either propofol or dexmedetomidine is advised. Neither agent is teratogenic. Whether benzodiazepine use results in an increased risk of congenital malformations remains unclear, although the majority of studies are reassuring. Thus, this class of drugs is best avoided in the first trimester and used sparingly thereafter (see www.reprotox.org) [55].
Neuromuscular blockers may be required during mechanical ventilation in a pregnant patient with severe ARDS. These agents should be used at the lowest dose possible and for the minimal amount of time necessary. Patients should have paralytic dosing titrated based upon a train-of-four testing. It is also suggested that awareness based upon objective brain function testing be performed while being chemically paralyzed, such as the bispectral index to assist in sedation titration [55]. Cisatracurium has a pregnancy risk factor rating of B and is the agent of choice in patients with either liver or renal failure because its clearance is via Hofmann degradation. Vecuronium and pancuronium are risk factor C in pregnancy, with pancuronium accumulating in patients with hepatic dysfunction [55].

Although sitting is usually the most advantageous position for weaning nonpregnant patients from mechanical ventilation, it may result in inferior vena cava compression in patients near term, in which case the left lateral decubitus position is preferable. Weaning parameters for pregnant patients are not well established, but it seems reasonable to follow the same guidelines as for nonpregnant patients (see Chapter 168).

Reversal of Hypotension

A mean arterial pressure ([2 × diastolic + systolic]/3) of 65 mm Hg, or greater, is recommended to optimize tissue perfusion and oxygenation. Supine recumbency may cause a significant decrease in venous return in women in their second or third trimester. To counteract this, the right hip should be elevated 10 to 15 cm (15 degrees) to move the uterus off the inferior vena cava, or the left lateral decubitus position should be used. As a corollary to this, if patients in the second or third trimester become hypotensive, placing them in the Trendelenburg position is unlikely to help and may actually decrease venous return because of vena cava compression.

When hypotension does not respond to measures to reduce uterine pressure on the vena cava, the fluid status of the patient should be assessed. If fluid boluses with 250 to 500 mL of saline do not resolve hypotension and the patient appears to be euolemic, vasopressors should be considered. The ideal vasopressor would restore maternal blood pressure without compromising uterine blood flow. Ephedrine, which has both α- and β-stimulating effects, tends to preserve uterine blood flow while reversing systemic hypotension related to epidural anesthesia [3]. Phenylephrine has been used alone or in combination with ephedrine to reverse maternal hypotension associated with epidural anesthesia [56]. The treatment guidelines for sepsis do not provide specific recommendations regarding vasopressors for pregnant women; however, following these guidelines for the management of maternal
hypotension from septic shock is reasonable [57]. The latest recommendations suggest norepinephrine as the first-line vasopressor in patients who fail to respond to fluid resuscitation [57]. There is no good data regarding the use of vasopressin for septic shock in pregnant women, although theoretically its use could cause uterine contractions by binding to uterine V1a receptors. One should balance the maternal and fetal risks and benefits if vasopressin is considered [55].

**Nutrition**

The importance of adequate nutrition during gestation is well recognized in that maternal weight gain correlates with fetal weight gain and a successful outcome. Maternal body stores are generally protected at the expense of fetal growth during semistarvation. The duration of starvation or semistarvation that can be tolerated without ill effects on the fetus is unknown. In addition, maternal malnutrition has been shown to correlate in certain cases with intrauterine growth retardation and development of preeclampsia [58]. It is also well recognized that hospitalized patients who have experienced prolonged starvation have greater problems with wound healing and that diminished protein stores are associated with increased susceptibility to infection.

For critically ill obstetric patients, nutritional support is thought to be important for both maternal and fetal outcomes. As with nonobstetric patients, enteral nutrition is preferred over parenteral nutrition to avoid the risk of complications associated with central venous catheters, to reduce expense, and to minimize intestinal mucosal atrophy [59]. Pregnancy is associated with decreased lower esophageal sphincter tone and decreased gastric motility; therefore, nasoduodenal tubes are preferred over nasogastric tubes to decrease the likelihood of reflux and aspiration, although scientific evidence for this is lacking.

Total parenteral nutrition (TPN) can provide complete nutritional support during pregnancy with good fetal outcomes and low maternal morbidity [58]. Given the stress of respiratory failure and its underlying causes, it seems reasonable to extend this experience with TPN to patients with respiratory failure who are unable to eat for more than 48 hours and whose gastrointestinal system cannot be used. Blood glucose levels should be measured, along with serum electrolyte concentrations, acid–base status, and renal and hepatic function. Measurement of trace element concentrations is needed for prolonged TPN. Periodic nutritional assessment should include evaluation of nitrogen balance, lymphocyte counts, transferrin, maternal weight, and fetal growth by ultrasound. Micronutrient monitoring and adequate administration of vitamins A, vitamin D, vitamin K, zinc, and folic acid are recommended for pregnant patients who require TPN. Deficiencies of these vitamins may lead to fetal
neural tube defects, eye abnormalities, and intracerebral hemorrhage [58]. If delivery occurs while the woman is receiving TPN, the neonate should be observed closely for hypoglycemia.

---

 Specific Therapy

**Thromboembolism**

Recommendations for the treatment of venous thromboembolic disease of pregnancy have been published by the American College of Chest Physicians (ACCP) [60]. When massive PE is strongly suspected (>50% occlusion of pulmonary vascular bed or systemic hypotension), the major immediate goals of therapy are to (a) provide adequate oxygenation as dictated by arterial blood gas analysis, (b) treat hypotension and organ hypoperfusion by elevating right ventricular preload with colloid or crystalloid administration and vasopressor therapy if necessary, and (c) interrupt clot propagation by immediate anticoagulation with intravenous heparin. Anticoagulation should be instituted immediately in all patients without clear contraindications, such as active bleeding, rather than delaying therapy pending conclusive diagnostic studies. The therapeutic options available include subcutaneous low molecular weight heparin (LMWH), intravenous unfractionated heparin (UFH), or subcutaneous UFH. Heparin is not teratogenic because it does not cross the placenta. Subcutaneous LMWH is preferred because of its safety profile, ease of administration, and efficacy [60]. Meta-analysis data in nonpregnant patients has shown that patients treated with subcutaneous LMWH for PE had decreased mortality, a reduction in thrombus size, and were less likely to experience a major hemorrhage [61].

Intravenous UFH is recommended in pregnant patients who have persistent hypotension as a result of PE or who are considered to be at a high risk of bleeding. Intravenous UFH has a short half-life and can be reversed quickly upon discontinuation and administration of protamine [60]. UFH would also be recommended for pregnant patients with severe renal failure rather than LMWH [60]. The half-life of LMWH is decreased in pregnancy, which may lead to subtherapeutic anticoagulation levels [60]. Routine monitoring of anti-Xa levels in all patients is not necessary. Patients with extremes of weight <50 kg or >90 kg, should be considered for anti-Xa monitoring every 4 to 6 weeks, so that twice-daily regimens achieve anti-Xa levels of 0.6 to 1.0 U per mL 4 hours postinjection [62].
When hemodynamic and angiographic information confirms massive PE, placement of a retrievable inferior vena cava filter is usually indicated to provide immediate and reliable prophylaxis against recurrent thromboembolism. Placement of a retrievable inferior vena cava filter is also advised in pregnant patients with thromboembolic disease and a contraindication to anticoagulation or for those patients who suffer recurrent PE on therapeutic anticoagulation [61]. In the case of massive life-threatening PE in a pregnant patient, thrombolytic therapy, mechanical fragmentation of thrombus and catheter-directed thrombolysis, or surgical embolectomy may be indicated [61].

Thrombolysis is not indicated for submassive PE, because large studies have failed to document that thrombolytic therapy results in any significant improvement in mortality or morbidity compared with heparinization [61]. However, in massive PE, randomized trials in nonpregnant patients have shown thrombolytic therapy to be effective in resolving thrombosis and improving hemodynamics. The overall incidence of bleeding related to thrombolysis is 8% [61]. No controlled trials of the use of thrombolytics in pregnancy have been reported.

A recent review identified 189 pregnant women who received thrombolytics during pregnancy for venous thromboembolism. No maternal mortality was reported, and the risk of major bleeding was 2.6% [62]. In a review of 13 patients who received thrombolytic therapy for PE during pregnancy, there were no maternal deaths, four nonfatal maternal major bleeding complications, two fetal deaths, and five preterm deliveries. The authors concluded that the fetal deaths and preterm deliveries were a consequence primarily related to the PE rather than thrombolytic therapy [64].

Recombinant tissue plasminogen activator is the recommended agent for thrombolysis. Streptokinase does not cross the human placenta, but streptokinase antibodies do cross [61]. Tissue plasminogen activator does not cross the placenta, and the risk of allergic reactions is lower than that of streptokinase. If thrombolytic therapy is used during pregnancy, it seems reasonable to limit the duration of therapy to the time needed for restoration of acceptable hemodynamic function and to discontinue therapy at least 4 to 6 hours antepartum. Continuous uterine massage and methylergonovine maleate should be used postpartum if thrombolytic therapy was only recently discontinued. Aminocaproic acid crosses the placenta readily and is teratogenic, so this should not be used when rapid reversal of the lytic state is needed before delivery. Cryoprecipitate and fresh-frozen plasma are used to rapidly reverse the lytic state.

Laboratory monitoring of the lytic state during thrombolytic infusion is not recommended, because clot lysis and risk of bleeding do not correlate well with laboratory measurement of the lytic state [65]. Following
completion of thrombolysis, heparin is administered once the activated partial thromboplastin time (aPTT) and thrombin time are less than twice the normal value [65]. If delivery is anticipated in the next 6 hours, initiation of heparin is delayed until after delivery.

Thrombolysis is contraindicated during delivery and the immediate postpartum state because of the bleeding risk. In these situations, surgical embolectomy may be a treatment option for massive PE when conventional therapy or thrombolytic therapy has failed, or if there is a contraindication for thrombolysis. There have been eight published cases in which pregnant women underwent surgical embolectomy for PE. There were no maternal deaths, although fetal death was reported in six cases and preterm delivery in four cases [64]. Surgical embolectomy should be reserved as a lifesaving measure for the mother because of the high incidence of fetal loss [64]. Catheter-directed therapy may include catheter-directed mechanical embolectomy and/or catheter-directed thrombolytic therapy. Among four cases using these techniques during pregnancy, one fetal death and one preterm delivery were reported [65].

Once the patient has stabilized, continuous intravenous heparin can be transitioned to subcutaneous therapy. This can be done with either LMWH or adjusted dose UFH to prolong the aPTT 1.5 to 2.5 times control. The patient should be anticoagulated for the remainder of the pregnancy and for at least 6 weeks postpartum [60]. If the PE occurs late in pregnancy or in the postpartum period, anticoagulant therapy should be continued for at least 6 months and, possibly, longer if persistent risk factors for a hypercoagulable state exist [60].

It is recommended that pregnant patients being treated with LMWH or UFH discontinue anticoagulation 24 hours prior to elective induction of labor [60]. If spontaneous labor occurs in a woman receiving adjusted doses of UFH, the aPTT should be monitored and corrected with protamine sulfate if delivery is near. Patients at high risk for recurrent thromboembolism during pregnancy should be placed on intravenous UFH, which can be discontinued 4 to 6 hours prior to expected delivery. This approach minimizes the period of time without therapeutic anticoagulation [60]. The timing of reinstitution of anticoagulation following delivery will vary depending upon the type of delivery, the presence of bleeding, and the presence of a neuraxial anesthesia catheter. As long as significant bleeding has not occurred, anticoagulation with a heparin may be resumed 6 hours after a vaginal birth or 12 hours after a cesarean section. However, after neuraxial anesthesia, therapeutic LMWH should be administered no earlier than 24 hours postoperatively.
The ACCP guidelines suggest limiting the use of fondaparinux and parenteral direct thrombin inhibitors in pregnant women to those with severe allergic reactions to heparin who cannot receive danaparoid [60]. In addition, the ACCP guidelines recommend avoiding the use of oral direct thrombin inhibitor (dabigatran) and anti-Xa inhibitors (rivaroxaban and apixaban) during pregnancy [60].

Amniotic Fluid Embolism

Treatment of AFE is limited to supportive measures aimed at providing adequate ventilation and oxygenation, maintenance of left ventricular output, blood pressure support, and management of bleeding. Most patients require intubation and mechanical ventilation. PEEP is helpful for oxygenation in some patients. No particular drug regimen has been used with any clear success to reverse pulmonary hypertension. If pulmonary capillary wedge pressures are elevated, it seems reasonable to use a diuretic to reduce hydrostatic pressures across the injured capillary endothelium. Measurement of changes in cardiac output can be used to guide this. In addition to fluid resuscitation to reverse hypotension, vasopressor therapy is frequently required.

Treatment of coagulopathy and hemorrhage in AFE requires aggressive blood and component replacement most easily managed utilizing massive transfusion protocols. For active bleeding, transfusion with red blood cells, fresh-frozen plasma, cryoprecipitate, platelets, and factor replacement is indicated. Manual massage and uterotonic medications are used to reduce uterine bleeding after delivery. When uterine bleeding is refractory to these interventions, exploration for uterine tears or retained placenta should be considered. Hysterectomy may be required to control bleeding if all other medical interventions fail. There are case reports describing maternal survival from AFE following treatment with intra-aortic balloon counterpulsation, extracorporeal membrane oxygenation, and cardiopulmonary bypass [67]. In addition, one patient was treated successfully with inhaled nitric oxide, recombinant human factor VIIa, and a right ventricular assist device [68].

In the event of a maternal cardiac arrest from AFE, an emergent perimortem delivery is indicated to improve the likelihood of a good newborn outcome, if the fetus is of a viable gestational age [17].

Venous Air Embolism

The goals of treatment are to identify the source of air entry, prevent further air entrainment, restore circulation, and remove embolized air. Placing the patient in the left lateral decubitus position may restore
forward blood flow by causing the bubble of air to migrate away from the right ventricular outflow tract to a nonobstructing position [19,29]. Closed-chest cardiac compression has also been reported to be helpful [20]. Aspiration of air from the right atrium, right ventricle, or pulmonary outflow tract can be attempted with a central venous or pulmonary artery catheter [19,20]. Air bubble resorption may be accelerated by ventilating the patient with 100% oxygen to facilitate diffusion of nitrogen from the embolus. When air embolism occurs during general anesthesia, nitrous oxide should be discontinued because it has a high solubility and tends to increase the size of air bubbles in the pulmonary vasculature [19,20].

Patients with continued evidence of neurologic deficits or cardiopulmonary compromise because of air embolism should be considered for hyperbaric oxygen therapy. Hyperbaric oxygen accelerates nitrogen resorption, decreases air bubble size, and increases the arterial oxygen content [19,20]. Use of anticoagulation with heparin has been suggested to treat fibrin microemboli, but has not been formally evaluated [19].

Aspiration of Gastric Contents

For patients with permeability pulmonary edema because of aspiration of gastric contents during labor and delivery, the main treatment is supportive care. Prophylactic antibiotics have not been found to be beneficial for aspiration pneumonitis [22]; therefore, antibiotics should be prescribed only when infection complicates the initial chemical pneumonitis. If the patient’s clinical course suggests development of bacterial pneumonia, the choice of antibiotic should be guided by appropriate bacteriologic evaluation of respiratory secretions, pleural fluid (if present), and blood cultures. For patients who have been in the hospital for 48 hours or less, clindamycin or a β-lactam–β-lactamase inhibitor combination is a reasonable empiric choice to treat anaerobic organisms. Glucocorticoids are not recommended in the treatment of aspiration events because of a lack of benefit found by two large multicenter randomized trials [22].

Respiratory Infections

Antibacterial agents to treat pneumonia during pregnancy should be selected according to the same principles used for nonpregnant patients [4,24,25]. Drugs with the least risk to fetus and mother should be chosen whenever possible [6]. For community-acquired pneumonia in pregnancy, penicillins, ceftriaxone, azithromycin, and erythromycin (excluding the estolate,
which is associated with an increased risk of cholestatic jaundice in pregnancy) are probably safe. Tetracycline is contraindicated because it is teratogenic and causes hepatic toxicity when administered intravenously in pregnancy. The aminoglycosides have the potential of causing eighth nerve toxicity in the fetus and should be used only when strong clinical indications exist. Serum drug levels should then be monitored closely. Sulfonamides are considered contraindicated at term because of the risk of neonatal kernicterus. Clindamycin has no reported adverse fetal effects, but experience is limited and it should be used with caution. Vancomycin hydrochloride may cause fetal renal and auditory toxicity and should be used with caution, with close monitoring of serum drug levels. Clarithromycin and levofloxacin are pregnancy risk factor class C and, therefore, should be used judiciously, weighing potential risks and benefits.

The predominant treatment of influenza pneumonia is supportive care, following the same practices as outlined for other causes of respiratory failure in pregnancy. The novel influenza A (H1N1) virus that appeared in 2009 is sensitive to the neuraminidase inhibitor antiviral medications such as oseltamivir and zanamivir, but it is resistant to the adamantane antiviral agents. It is recommended that pregnant women with a confirmed, probable, or suspected case of influenza A (H1N1) receive empiric institution of oseltamivir for a period of 5 or more days. Treatment should be started although results from testing are pending, because the maximal clinical benefit is seen when antiviral therapy is begun within 48 hours of the onset of symptoms \[26,69\]. Adamantanes are no longer recommended for influenza owing to concerns about antiviral resistance in the circulating influenza strains \[69\]. Fetal side effects have not been reported with either neuraminidase inhibitor, although experience with them is limited.

Intravenous acyclovir has been shown to decrease maternal mortality from varicella pneumonia. Acyclovir has not been shown to be teratogenic when used during human pregnancy. The recommended dosing is 10 mg per kg every 8 hours intravenously, with adjustments made for renal insufficiency. The recommended length of therapy is 7 days. Maintenance of a euvoletic fluid status minimizes renal impairment secondary to acyclovir. Initiation of acyclovir at the first evidence of respiratory system involvement in pregnant patients with cutaneous varicella infection optimizes the chances of a favorable outcome. Infants born to women in whom varicella infection developed within 4 days of delivery should receive varicella-zoster immune globulin
within 72 hours of birth [70].

Amphotericin B is the drug of choice for severe disseminated coccidioidal infection during pregnancy [30]. Azoles are contraindicated during pregnancy: fluconazole exposure is teratogenic in the first trimester; and voriconazole is category D owing to documented fetal harm and teratogenicity. There is not enough safety data to recommend caspofungin during pregnancy. Amphotericin has been used with success in disseminated coccidioidal infection during pregnancy. It crosses the placenta and is present in umbilical cord serum at a concentration one-third of the maternal serum concentration. However, it does not appear to have an adverse effect on fetal development; normal, full-term infants have been born to women who received amphotericin B during the first trimester, as well as later in gestation. Because anemia and nephrotoxicity often occur during the course of amphotericin B therapy, blood cell counts and renal function should be monitored closely [30].

Active TB has been treated with modern chemotherapeutic agents with excellent maternal and fetal outcome. The initial treatment regimen should consist of isoniazid, rifampin, and ethambutol for a minimum of 9 months [32]. In the United States, pyrazinamide is not recommended for use during pregnancy [32]. Streptomycin has been associated with fetal hearing loss and vestibular dysfunction and should be avoided [32]. Ethionamide has been identified as a teratogen [32].

Treatment of PCP during pregnancy includes trimethoprim–sulfamethoxazole, with the addition of glucocorticoids for severe disease characterized by a PaO$_2$ less than 70 mm Hg or an alveolar–arterial oxygen gradient of more than 35 mm Hg [71]. For _L. monocytogenes_–associated pneumonia in pregnancy, high-dose ampicillin is the treatment of choice (2 g intravenously every 4 hours) for at least 14 days [72].

**Asthma**

The Working Group on Asthma and Pregnancy of the National Asthma Education Program has published a report summarizing the available data for asthma medications and management during pregnancy [73]. The first priority of therapy for pregnant women with asthma is to prevent or reverse the hypoxemia that, to some degree, accompanies virtually every exacerbation of asthma. Oxygen should be used in all asthmatic patients who present to the hospital with an exacerbation; the goal oxygen saturation is 95% or higher because hypoxemia may worsen initially with bronchodilator therapy, as a result of worsening ventilation–perfusion mismatch. Other therapies are directed at the rapid reversal of bronchoconstriction and airways inflammation (see Chapter 172).
Bronchoconstriction is managed with inhalation of selective rapid-onset $\beta_2$-agonist and anticholinergic agents, given at 20-minute intervals or continuously. Typically, nebulized medication is given prior to intubation and then switched to metered dose inhaler after intubation. The doses of albuterol and ipratropium are the same for both obstetric and nonobstetric patients presenting with status asthmaticus [73]. The effects of inhaled agents are predominantly local, which should decrease the amount of fetal exposure, and selective $\beta_2$-agonists do not adversely affect uterine blood flow. There has been no evidence of fetal injury from the use of either systemic or inhaled $\beta$-adrenergic agonists [73], although neonates exposed to systemic $\beta$-agonists just prior to delivery have demonstrated tachycardia, hypoglycemia, and tremor. These effects do not constitute a contraindication to the use of $\beta$-adrenergic agents.

Systemic glucocorticoids should be initiated promptly in all pregnant patients presenting with an acute asthma exacerbation who are not responding to one or two inhalational treatments with a $\beta_2$-agonist [73]. Institution of glucocorticoids helps to reverse airflow obstruction and, thereby, decrease the amount of high-dose $\beta$-adrenergic agonist therapy needed. The optimal dose of systemic glucocorticoid in this setting is not known. However, the same dose ranges are used in both obstetric and nonobstetric adults, prednisone or methylprednisolone 120 to 180 mg per day in three or four divided doses for the first 48 hours and then 40 to 60 mg a day until clinical improvement is significant and the peak expiratory flow has increased to 70% of predicted or personal best [73]. Further tapering is based on the response to treatment.

Prednisone and prednisolone cross the placenta poorly [73]. In rodents that were given glucocorticoids during gestation, an increased prevalence of spontaneous abortions, placental insufficiency, and cleft palate were found; it remains controversial whether a slight increase in risk of cleft palate pertains in humans [73]. Chronic maternal ingestion of systemic glucocorticoids has been associated with lower birth weight and increased incidence of premature deliveries [74].

In general, intravenous theophylline is not used during treatment of acute asthma exacerbations because of the lack of evidence of benefit [73]. However, for patients who normally take theophylline, the medication is normally continued during the hospitalization. If the patient is unable to take oral medication, intravenous theophylline is usually substituted, but without a loading dose. Because toxicity can develop in the fetus when theophylline is administered at the time of delivery [73], serum levels should be closely followed and kept below 15 mg per mL.

In patients with severe bronchoconstriction, who are refractory to inhaled nebulized albuterol sulfate, parenteral agents such as terbutaline sulfate, 0.3 mg, or epinephrine, 0.3 mL of a 1 to 1,000 solution, may
rarely be given subcutaneously. A major concern is that epinephrine may cause uterine artery vasoconstriction through its α-adrenergic effects; this potential risk would have to be balanced against the need to reverse refractory bronchoconstriction.

In the management of an acute exacerbation of asthma for a pregnant woman, monitoring of the respiratory rate and PaCO₂ levels is critical in the identification of impending respiratory failure. Normalization of the PaCO₂ in a pregnant patient may be the indication of respiratory muscle fatigue, and ventilatory support is indicated. Early intervention with noninvasive ventilation and/or intubation with ventilatory support should be seriously considered.

For patients who are extremely difficult to manage even with therapeutic levels of bronchodilators, high-dose glucocorticoids, and mechanical ventilation, a few less-studied therapeutic interventions such as intravenous magnesium sulfate and inhaled isoflurane can be considered. None of these interventions have been studied in pregnancy, so their use should be limited to situations in which the woman’s life is in danger and all other forms of therapy have failed (see Chapter 172, for a full discussion).

Once a pregnant woman reaches the point of life-threatening refractory asthma, emergent delivery of the fetus by cesarean section should be considered. There have been anecdotal reports of significant maternal improvement after delivery of the fetus. The decision for urgent delivery is complicated and depends in part on the gestational age of the fetus and the clinical status of the mother.

Pneumomediastinum and Pneumothorax

The natural history of pneumomediastinum is spontaneous resolution within 3 to 14 days without permanent sequelae. Pneumomediastinum does not usually require drainage in adults because the air usually dissect out of the mediastinum into the subcutaneous tissues of the neck. Thus, treatment should be directed at improving any underlying predisposing cause, such as asthma, if present. Supplemental oxygen may promote reabsorption of the mediastinal air.

A spontaneous pneumothorax occupying less than 20% of the hemithorax in an asymptomatic patient not on mechanical ventilation can be monitored closely without immediate insertion of a chest tube. Supplemental oxygen should be administered to accelerate the resolution
of the pneumothorax. In patients who are symptomatic, on mechanical ventilation, or have an enlarging pneumothorax, chest tube placement is mandatory. Patients whose pneumothorax develops as a complication of barotrauma during mechanical ventilation may also require adjustments in the ventilator settings to reduce airway pressures and further barotrauma.

Patients with an existing pneumothorax or history of one in the past are at increased risk of worsening or recurrence of pneumothorax during labor and delivery, particularly during the Valsalva maneuvers at parturition. Although formal evidence is lacking, use of epidural analgesia and assisted vaginal delivery is suggested to avoid prolonged Valsalva maneuvers [45]. For patients requiring cesarean section, analgesia with epidural anesthetic is preferred to general anesthesia with positive pressure ventilation.

The recurrence rate of ipsilateral spontaneous pneumothorax is 30% to 50% within 5 years without pleurodesis [45]. Pleurodesis with any tetracycline derivative through a chest tube is contraindicated in pregnancy because of possible fetal exposure. It is recommended that minimally invasive elective video-assisted thoracoscopic surgery (VATS) with bleb resection and mechanical pleurodesis be considered in the subsequent convalescent period to prevent a recurrent pneumothorax [45]. Thoracotomy or VATS with bleb resection and pleurodesis is indicated for pregnant patients with continued air leak and incomplete lung expansion [77]. Tocolytic therapy may be required to prevent preterm labor during this surgical intervention.
Thromboembolic Disease

Preventing DVT is probably the most important intervention to reduce maternal mortality caused by PE. Patients who require bed rest or surgery during pregnancy should be treated prophylactically with an LMWH regimen such as dalteparin 5,000 U subcutaneously every 24 hours or enoxaparin 40 mg subcutaneously every 24 hours. In the setting of impaired creatinine clearance, UFH 5,000 U subcutaneously every 12 hours may be used [60]. Warfarin crosses the placenta and is teratogenic, so its use is contraindicated in pregnancy [60]. Patients who are receiving ongoing warfarin therapy for prior thromboembolic disease should be changed to subcutaneous heparin therapy before conception or at least before the sixth week of pregnancy. LMWH is recommended for prophylaxis and treatment because of the reduced risk of bone loss and heparin-induced thrombocytopenia as compared with UFH [60].

Pregnant women with a history of thromboembolic disease and/or hypercoagulable state should receive thromboembolic prophylaxis throughout pregnancy and for 4 to 6 weeks postpartum [60]. The ACCP guidelines recommend either prophylactic or intermediate-dose regimens of LMWH or UFH for these particular subgroups of pregnant patients (Table 164.3) [60]. Once adequate hemostasis has been accomplished postpartum, subcutaneous anticoagulation therapy can be resumed and continued until 6 weeks postpartum. Alternatively, warfarin can be added to subcutaneous heparin, and the heparin stopped when therapeutic prolongation of the International Normalized Ratio is achieved.

</table>
Adjusted dose UFH: UFH subcutaneously every 12 hours adjusted to target an aPTT into therapeutic range

LMWH, low molecular weight heparin; UFH, unfractionated heparin; aPTT, activated thromboplastin time.

Aspiration of Gastric Contents

Based on national surveys of obstetric practice, antacid administration, H$_2$ blockade, or proton pump inhibitors have been used for aspiration prophylaxis in pregnant women who require general anesthesia or analgesic therapy other than local or epidural anesthetics [22]. This is done despite the lack of complete protection achieved with gastric pH values greater than 2.5 and a recent meta-analysis that showed no evidence that any of these medications reduced the incidence of gastric aspiration [22,78]. Some authors recommend that all women in labor receive nothing by mouth except medications. This should probably be individualized, in view of the low risk of aspiration during spontaneous vaginal delivery in nonsedated patients and the small proportion of patients who require emergent general anesthesia.
RESPIRATORY INFECTIONS

Immunization is the most effective method to prevent influenza pneumonia. The Advisory Committee on Immunization Practices currently recommends the administration of the inactivated influenza vaccine for all pregnant women and also the intranasal flu vaccine should not be given to pregnant women because it contains a live-attenuated virus [79]. The parenteral influenza vaccine contains inactivated virus and is not associated with adverse pregnancy outcomes. Maternal vaccination will also protect newborn infants from influenza, which is important as infants <6 months are at increased risk of influenza-associated complications and are not eligible to receive influenza vaccination. In addition, influenza vaccination is recommended for all women who will be pregnant during the influenza season and should be administered between October and mid-November regardless of the trimester of pregnancy [79].

β-Adrenergic Tocolytic Therapy

The epidemiologic factors that place patients at increased risk for tocolytic-induced pulmonary edema include longer duration of intravenous β-adrenergic tocolytic therapy (24 to 48 hours), large volume of crystalloid infusion, multiple gestation, concomitant sepsis, and, possibly, preeclampsia [16]. If a β-adrenergic tocolytic agent must be used, limiting the intravenous phase of β-adrenergic therapy to less than 24 to 48 hours and adjusting the dose to keep the maternal heart rate under 120 beats per minute may reduce complications. The β-adrenergic agent should be discontinued immediately at the earliest sign of respiratory distress, such as chest pain, tachypnea, dyspnea, or reduced oxygen saturation. Careful fluid balance records should be maintained, and fluid restriction and, possibly, diuresis should be considered when intake exceeds output by greater than 500 mL. Sodium intake should be restricted to 4 to 6 g per day. If glucocorticoids are required to enhance fetal lung development, a formulation with the lowest mineralocorticoid potency should be used. Clinical improvement in tocolytic-induced pulmonary edema usually occurs within 12 hours after the drug is discontinued and diuresis is begun [16].

Patients with underlying cardiac disease, particularly structural defects causing outflow obstruction, should be excluded from β-adrenergic
tocolytic therapy. Patients with severe preeclampsia would likely benefit more from early delivery than from combining the increased risks of tocolytic therapy with those of continuing pregnancy-induced hypertension.

Advances in management of pregnancy based upon randomized controlled clinical trials are summarized in Table 164.4.

**TABLE 164.4 Advances in Management of Acute Respiratory Failure in Pregnancy based upon Clinical Trials**

- Mechanical ventilation of a pregnant patient with ARDS should follow the guidelines of the ARDS Network Study [53]. B
- Unfractionated heparin remains the drug of choice for massive pulmonary embolism during pregnancy [60]. D
- Low molecular weight heparin is safe and effective in pregnancy, and may be used for anticoagulation for pulmonary embolism during pregnancy once the patient is stabilized [60]. D
- Pregnancy is a relative contraindication for thrombolytic therapy. Thrombolysis has been used safely in life-threatening pulmonary embolism during pregnancy with maternal mortality of 1% and fetal loss 6%. Recombinant tissue plasminogen activator and streptokinase are the recommended thrombolytics during pregnancy [63]. D

ARDS, acute respiratory distress syndrome; B, 1 RCT trial; D, nonrandomized, contemporaneous control group.

Extrapulmonary Causes of Respiratory Failure
HELEN M. HOLLINGSWORTH • RICHARD S. IRWIN

The conditions that cause respiratory failure primarily by their effect on structures other than the lungs are discussed in this chapter. Severe impairment of the extrapulmonary compartment produces respiratory failure through the mechanism of hypoventilation, so the resultant respiratory failure is always hypercapnic. Extrapulmonary causes account for up to 17% of all cases of hypercapnic respiratory failure [1]. This chapter is organized to follow sequential sections of pathophysiology, diagnosis, differential diagnosis, and treatment.

PATHOPHYSIOLOGY

The extrapulmonary compartment includes the (a) central nervous system (CNS), (b) peripheral nervous system, (c) respiratory muscles, (d) chest wall, (e) pleura, and (f) upper airway [2]. Because many conditions can cause extrapulmonary respiratory failure, it is helpful to categorize them according to the specific component affected by the disease process (Fig. 165.1). We have limited the discussion that follows to descriptions of the individual diseases and conditions that are most important to the topic of respiratory failure. They are summarized in Tables 165.1 through 165.4.

↓, decreased; ↑, increased; CPAP, continuous positive airway pressure; CT, computed tomography; PFT, pulmonary function test.

Functionally, extrapulmonary disorders can lead to hypercapnic respiratory failure caused by a decrease in normal force generation (e.g., CNS dysfunction, peripheral nervous system abnormalities, or respiratory muscle dysfunction) or an increase in impedance to bulk flow ventilation (e.g., chest wall and pleural disorders or upper airway obstruction) [3].
DIAGNOSIS

General Considerations

Arterial hypercapnia in the presence of a normal alveolar–arterial oxygen tension [P(A–a)O$_2$] gradient on room air is the sine qua non of extrapulmonary respiratory failure [4]. The normal gradient reflects the fact that, in pure extrapulmonary failure, distal gas exchange is normal, and the decrease in the partial pressure of arterial oxygen (PaO$_2$) directly reflects the decrease in the partial pressure of alveolar oxygen (PAO$_2$). A P(A–a)O$_2$ gradient of less than 20 mm Hg in the presence of an elevated partial pressure of carbon dioxide (PaCO$_2$) is, with few exceptions, diagnostic of extrapulmonary respiratory failure [5–11]. The main exception occurs for patients with chronic obstructive pulmonary disease (COPD) who have increasing hypercapnia [12]. Their P(A–a)O$_2$ gradient can occasionally narrow to normal, probably related to substantial changes in the position of the alveolar and arterial points on the oxyhemoglobin dissociation curve related to ventilation–perfusion inequalities [12]. Thus, arterial hypercapnia with a normal P(A–a)O$_2$ gradient is consistent with pure extrapulmonary respiratory failure, but a normal P(A–a)O$_2$ cannot, by itself, rule out severe COPD.

Pulmonary parenchymal disease can also exist concomitantly with extrapulmonary dysfunction. For example, a patient with polymyositis can have respiratory muscle weakness in addition to interstitial lung disease. This coalescence of clinical processes may be suggested by the combination of hypercapnia and only mild-to-moderate widening of the P(A–a)O$_2$ gradient. A gradient between 20 and 30 mm Hg in the presence of arterial hypercapnia should raise the suspicion that a significant element of extrapulmonary dysfunction may be present. It is also important to realize that even when the P(A–a)O$_2$ gradient exceeds 30 mm Hg, some degree of extrapulmonary dysfunction can also be present in association with significant pulmonary impairment. For example, when hypercapnic respiratory failure results from an acute exacerbation of COPD, respiratory muscle fatigue often contributes to the development of carbon dioxide retention [13]. A less common example is the presence of a large abdominal ventral hernia in a patient with COPD. The resultant paradoxical breathing pattern can contribute significantly to abnormal gas exchange and increased dyspnea [14].
Decrease in Normal Force Generation

Because the inspiratory muscles generate the force that results in ventilation, any condition that directly or indirectly impairs respiratory muscle function can result in decreased force generation [3]. Dysfunction of the respiratory center, peripheral nervous system pathways, or the respiratory muscles themselves decreases the force available to produce ventilation. If this impairment is severe enough, the level of minute ventilation will be insufficient to clear the amount of carbon dioxide produced by ongoing metabolic processes and hypercapnic respiratory failure results.

An acute decrease in CNS output sufficient to result in hypercapnic respiratory failure (e.g., acute narcotic overdose) is usually accompanied by obvious evidence of generalized CNS depression. In contrast, a chronic (e.g., primary alveolar hypoventilation) or episodic (e.g., central sleep apnea) cause of decreased impulse formation may present a much more difficult diagnostic dilemma. Tests to evaluate respiratory center drive, such as voluntary hyperventilation, carbon dioxide stimulation, or polysomnography, may be necessary to define the problem.

Peripheral nervous system dysfunction or primary weakness of the respiratory muscles is often indicated by the presence of certain suggestive clinical findings that vary depending on the specific entity present (see the following discussion). Respiratory muscle fatigue or weakness may be suspected clinically and documented using a number of tests designed to evaluate respiratory muscle function.

Symptoms are usually nonspecific; patients may report dyspnea on exertion, either when supine (bilateral diaphragmatic paralysis) or when upright (C5 to C6 quadriplegia). Reports of weakness in other muscle groups, difficulty swallowing, and change in voice volume or tone may be other clues. Physical findings of changes in the rate, depth, and pattern of breathing suggest stressed, fatigued, or weakened respiratory muscles. For example, an increased respiratory rate, a decreased tidal volume, and paradoxic inward motion of the anterior abdominal wall during inspiration may be observed. The latter finding indicates a failure of the diaphragm to contract sufficiently to descend and move the abdominal contents downward and the abdominal wall outward during inspiration. A breathing pattern that cycles between predominantly chest wall and predominantly abdominal wall motion, called respiratory alternans, represents the alternating contraction of intercostal and accessory muscles, on the one hand, and the diaphragm, on the other. The
assumption is that these two muscle groups alternate in their contribution to the work of breathing, allowing one another to rest during periods of muscle overload or fatigue.

Two readily available tests can be useful diagnostically to help assess respiratory muscle function. First, measurement of maximal inspiratory and expiratory pressures at the mouth is easy to perform, noninvasive, and can accurately predict the development of hypercapnic respiratory failure caused by decreased respiratory muscle force generation [15,16]. Arterial hypercapnia caused by respiratory muscle weakness is generally not seen until the maximal inspiratory pressure is reduced to 30% or less of normal [15,16]. Although normal predicted values vary (primarily on the basis of age and gender) [17,18], a maximal inspiratory pressure less negative than −30 cm H₂O is likely to be associated with arterial hypercapnia [16,19]. Maximal expiratory pressures are also reduced when there is respiratory muscle weakness, and, in some neuromuscular disorders, the decrease may be even greater than that of the corresponding inspiratory pressure [16]. A maximal expiratory pressure of less than 40 cm H₂O is generally associated with a poor cough and difficulty clearing secretions [19].

A second measurement that is valuable in predicting the development of arterial hypercapnia caused by neuromuscular weakness is the vital capacity. It can be performed either in the pulmonary function laboratory or at the bedside [15,19]. Although a vital capacity of less than 1 L, or less than 15 mL per kg of body weight is commonly associated with arterial hypercapnia [1,19], the vital capacity is a less sensitive predictor of arterial hypercapnia than is the maximal inspiratory pressure, particularly in patients with chest wall disorders such as kyphoscoliosis [16]. Significant arterial hypercapnia is unlikely to occur with an inspiratory pressure more negative than −30 cm H₂O; however, arterial hypercapnia may be present with a vital capacity as high as 55% or as low as 20% of the predicted value [15,16].

The measurement of transdiaphragmatic pressures (P_{di}) and diaphragmatic electromyograms (EMGs), although not commonly used clinically, may be helpful. An inspiratory effort associated with a P_{di} consistently more than 40% of maximum predictably results in diaphragmatic fatigue [20]. Therefore, it follows that patients with diaphragmatic weakness and a reduced maximum P_{di} are at risk for developing diaphragmatic fatigue and respiratory failure, even in the face of normal inspiratory pressure [20]. Similarly, a decrease of more than 20% from baseline in the high- to low-frequency ratio as measured by the diaphragmatic EMG indicates diaphragmatic fatigue and portends the development of hypercapnic failure [21,22].

For those readers interested in assessing diaphragm function with
point of care ultrasonography, a section discussing this can be found in Chapter 168 on Discontinuation of Mechanical Ventilation.

Central Nervous System Dysfunction

The respiratory center, located in the brainstem, is composed of two main parts, the medullary center and the pneumotaxic center [23,24]. The medullary center is responsible for initiation and maintenance of spontaneous respiration, and the pneumotaxic center in the pons helps coordinate cyclic respiration. A decrease in central drive can occur owing to a direct central loss of sensitivity to changes in PaCO\textsubscript{2} and pH or a peripheral chemoreceptor loss of sensitivity to hypoxia as a result of CNS depressants, metabolic abnormalities, structural lesions, primary alveolar hypoventilation, and central sleep apnea (Table 165.1) [25–43].

Peripheral Nervous System Dysfunction

Disruption in impulse transmission from the respiratory center to the respiratory muscles can eventuate in respiratory failure. This disruption can be caused by spinal cord disease [44], anterior horn cell disease [45,46], peripheral neuropathy, or neuromuscular junction blockade [19] (Table 165.2) [5,25,44–88]. Denervation of the inspiratory muscles may occur as part of a generalized process (e.g., Guillain–Barré’s syndrome, myasthenia gravis [19]) or as an isolated abnormality (e.g., phrenic nerve palsy secondary to hypothermic cardioplegia during cardiac surgery [67,89]).

Peripheral nervous system dysfunction severe enough to produce hypercapnic respiratory failure is always associated with pulmonary function test findings of a reduced vital capacity (usually less than 50% of the predicted value [15,19]) and markedly decreased maximal inspiratory and expiratory pressures (usually 30% of the predicted pressures [15,19,55]). This type of respiratory failure is characterized by an ineffective cough and a high incidence of aspiration, atelectasis, and pneumonia [5].

The effect on the respiratory system of interruption of CNS impulse transmission as a result of spinal cord abnormalities is highly dependent on the level of the injury [44,47]. A lesion at the C3 vertebral level or above abolishes both diaphragmatic and intercostal activities, leaving only some residual accessory muscle function [47]. The result is severe hypercapnic respiratory failure. Acute spinal cord lesions at the C5 and C6 levels produce an immediate fall in the vital capacity to 30% of the predicted value, owing to loss of intercostal and abdominal muscle function [44]. This is associated with a limitation of both inspiratory capacity and active expiration. Within approximately 3 months of injury,
however, the denervated muscles become stiff, which enables improved
diaphragmatic efficiency. This improvement usually leads to an increase
in the vital capacity to 50% to 60% of normal. Mid-thoracic spinal cord
lesions have relatively little impact on respiratory muscle function
because they principally affect the abdominal muscles, resulting in only a
limitation of active expiration and cough [5,47].

Most spinal cord diseases interrupt impulse transmission, resulting in
respiratory muscle weakness, but two notable exceptions exist: tetanus
and strychnine poisoning. In both conditions, inhibitory influences at the
spinal cord and anterior horn cell level decrease [51,52], causing a
simultaneous increase in motor activity to groups of muscles that are
normally antagonistic to one another. This results in intense muscle
spasms, including involvement of the upper airway muscles, diaphragm,
and intercostal muscles. The repetitive spasms and episodes of apnea
result in severe arterial hypoxemia, hypercapnia, metabolic acidosis, and
rhabdomyolysis [51,52].

Diseases that involve the anterior horn cells of the spinal cord interrupt
efferent impulse transmission. Amyotrophic lateral sclerosis (ALS) is the
most common anterior horn cell disease causing respiratory failure
[5,45,47]. In most cases of ALS, the patient develops segmental muscular
atrophy, weakness of the distal extremities, hyperreflexia, fasciculations,
and bulbar paralysis [45]. Although respiratory failure usually develops
late in the course of the disease, it may rarely be the presenting
manifestation [45]. Repetitive episodes of aspiration secondary to bulbar
dysfunction may contribute to respiratory impairment [4]. It has been
speculated that antecedent poliomyelitis may be involved in some cases
of ALS [53]. A post-polio syndrome, characterized by new, slowly
progressive muscle weakness, may develop years after recovery from
acute poliomyelitis [57].

Polyneuropathies with prominent motor neuron involvement, (e.g.,
Guillain–Barré’s syndrome) can affect the respiratory nerves and lead to
respiratory failure (see Chapter 152) [25]. Symmetric, predominantly
distal muscle weakness with absent tendon reflexes is the typical
presentation [25]. In one series of patients with Guillain–Barré’s
syndrome, 28% required mechanical ventilatory assistance. The average
duration of mechanical ventilation was 9 weeks (range, 3 weeks to 7
months). Although the mortality rate is generally low, 21% of hospitalized
patients died in one series [90]. Guillain–Barré’s syndrome may be
associated with autonomic dysfunction in approximately two-thirds of
patients, including tachyarrhythmias and bradyarrhythmias, blood
pressure fluctuations, abnormal hemodynamic responses to drugs, flushing and sweating, pupillary light unresponsiveness, and also bladder and bowel dysfunction (e.g., ileus) [90].

Dinoflagellate toxin poisoning, from red tide-contaminated shellfish and ciguatera-contaminated reef and other fish, is a dramatic but uncommon cause of peripheral neuropathy resulting that can produce respiratory failure [61–66]. The responsible agents are heat-stable neurotoxins that interfere with action potential propagation along peripheral nerves. During the warm summer months, the dinoflagellates that produce the toxins proliferate and are ingested by shellfish and fish. The clinical picture is virtually pathognomonic. Within 30 minutes of ingesting contaminated shellfish, tingling and numbness of the face, lips, and tongue develop. Paresthesias and muscle weakness follow, with rapid progression to limb and respiratory muscle paralysis [62,63]. Multiple-case presentations from one source of exposure are common.

Peripheral phrenic nerve palsies can contribute to or cause hypercapnic respiratory failure, particularly if they are bilateral [91]. Bilateral phrenic nerve palsies have been described as an uncommon complication of hypothermia used for cardioplegia during cardiac surgery (particularly when ice slush is used) [67], trauma [67,91], a variety of neurologic diseases (e.g., poliomyelitis and Guillain–Barré’s syndrome) [67,68,91], Charcot–Marie–Tooth’s disease [70], intrathoracic malignancies [92], and as a part of a paraneoplastic syndrome [93]. Bilateral diaphragmatic paralysis can also be idiopathic [94]. The characteristic clinical findings of bilateral diaphragmatic paralysis are severe orthopnea and marked abdominal paradoxical muscle movement in the supine position [69,89,91,95]. Fluoroscopy during a sniff test is more helpful in identifying unilateral than bilateral diaphragm paralysis, because upward motion of the ribs during inspiration when there is bilateral paralysis can make the diaphragm appear to descend. The diagnosis of diaphragmatic paralysis is usually confirmed by transdiaphragmatic pressure measurements that reveal a minimal or an absent $P_{di}$ gradient [91]. Electromyography of the diaphragm and phrenic nerve conduction velocity studies may also be helpful.

Several other causes of peripheral neuropathy can involve the efferent pathways to the respiratory muscles, including diphtheria, herpes zoster infection, tick paralysis, acute intermittent porphyria, beriberi, and a variety of metabolic disorders [25]. Respiratory failure associated with diphtheria is of delayed onset, usually occurring 4 to 6 weeks after the onset of illness [25]. Tick paralysis is seen mainly in children in whom the
presence of the tick goes unnoticed for 5 to 6 days [25]. In acute intermittent porphyria, respiratory involvement may be a slowly progressive process or may cause an abrupt deterioration in respiratory function as a result of bilateral phrenic nerve paralysis [37]. Myasthenia gravis [19], botulism [84–86], organophosphate poisoning [25], and a variety of drugs can produce neuromuscular blockade that results in respiratory failure [76]. Although patients with myasthenia gravis typically show signs of obvious muscle weakness and rapid fatigability, particularly of the cranial muscles, before the development of respiratory failure, acute respiratory failure is occasionally a presenting manifestation [19,25,72]. More commonly, respiratory failure complicates myasthenia gravis after surgical procedures, following the institution of glucocorticoid therapy, or as a result of under- or overtreatment with anticholinesterase medications [19].

Although the diagnosis of myasthenia gravis is suspected on clinical grounds and a positive response to edrophonium chloride (Tensilon) is supportive, the diagnosis is confirmed by a typical EMG (decremental responses on repetitive nerve stimulation) and an elevated serum level of antibodies to acetylcholine receptors [19,71] (see Chapter 153). Part of the management of a patient with myasthenia gravis includes serial measurement of the maximum inspiratory pressure and vital capacity to assess the risk for respiratory failure [25]. A decrease in vital capacity to less than 20 mL per kg, in maximum inspiratory pressure to less negative than −30 cm H₂O, or in maximum expiratory pressure to less than 40 cm H₂O is a warning sign of impending respiratory failure [19].

Eaton–Lambert’s syndrome, a form of neuromuscular blockade similar to myasthenia gravis, occurs in association with certain carcinomas, particularly small cell carcinoma of the lung [55,56]. The neuromuscular blockade in most cases precedes other evidence of the carcinoma, and the EMG shows an incremental pattern unlike that in true myasthenia.

Critical illness polyneuropathy occurs in the setting of sepsis and multiorgan failure in up to 30% of patients by clinical examination and up to 70% by electrophysiologic testing [78,81]. Profound generalized muscle weakness as a result of critical illness polyneuropathy is a major reason why these patients often require prolonged mechanical ventilatory support. Similar to patients with Guillain–Barré’s Syndrome, patients with critical illness polyneuropathy also have areflexia, but in contrast, they may also have prominent sensory nerve deficits and a normal cerebrospinal fluid examination. Electrophysiologic testing helps to distinguish critical illness polyneuropathy from Guillain–Barré’s syndrome; in critical illness, polyneuropathy nerve conduction studies show axon degeneration rather than demyelination. Although the etiology of critical illness polyneuropathy is not known, it is predominantly a disease of older patients who stay in the intensive care
unit for more than 28 days and who have elevated serum glucose and decreased albumin levels at the time of diagnosis. Approximately half of patients with sepsis, multiorgan system failure, and critical illness polyneuropathy survive, and the prognosis of survivors for significant improvement from the neuropathy is good [79] (for additional details, see Chapter 154).

Prolonged administration (longer than 2 days) of neuromuscular blocking agents (NMBAs), such as pancuronium and vecuronium, has been associated with two distinct patterns of neuromuscular dysfunction [82]: (a) persistent neuromuscular junction blockade in patients with renal insufficiency who accumulate the parent drug and its active metabolites and (b) an acute noninflammatory myopathy that becomes apparent as neuromuscular transmission improves. The myopathy appears to be a consequence of an interaction between NMBAs and glucocorticoids and seems to be related to the total dose and duration of action of the NMBA [83]. This has been particularly dramatic in previously healthy asthmatic patients, approximately 15% of whom develop muscle weakness after short-term use of an NMBA and high-dose glucocorticoids [82]. In a systematic review of trials of cisatracurium administered by infusion for 48 hours to patients with acute respiratory distress syndrome (ARDS) (431 patients of which 190 received glucocorticoids), no increased risk of critical illness-acquired weakness was noted in the cisatracurium groups [83]. In general, it appears that NMBA given for short periods appear safe for patients with ARDS; further testing is needed in additional populations, particularly those receiving higher doses of systemic glucocorticoids.

Neuromuscular blockade may also occur as a result of administration of a variety of other drugs [76]. Certain cardiovascular drugs (e.g., lidocaine, quinidine, procainamide, and propranolol), anticonvulsants (e.g., phenytoin and trimethadione), D-penicillamine, and a number of antibiotics (most notably the aminoglycosides) can prolong postoperative respiratory depression, unmask underlying myasthenia gravis, or cause a drug-induced form of myasthenia gravis [76]. The definitive diagnosis of drug-induced neuromuscular blockade is usually made in retrospect if the abnormality reverses after elimination of the offending agent. In some cases, the administration of calcium gluconate has been reported to result in prompt improvement in neuromuscular transmission [76].

Prolonged neuromuscular blockade is occasionally seen after the administration of succinylcholine in individuals with pseudocholinesterase deficiency [25]. In contrast to the usual duration of
paralysis of approximately 3 minutes, the effect in these individuals usually lasts 4 to 6 hours, during which time they require mechanical ventilatory support [25].

In botulism, neuromuscular blockade develops as a result of a neurotoxin produced by the bacteria Clostridium botulinum. Most cases are caused by neurotoxin-contaminated food [84–86], but, occasionally, botulism develops as a result of a wound infected with C. botulinum [51] (see Chapter 86). Certain findings help to predict whether respiratory failure requiring mechanical ventilation will develop. A vital capacity of 30% or less of the predicted value is generally associated with hypercapnic failure [50]. Other clues are the presence of nausea, vomiting, diarrhea, dyspnea, ptosis, or extremity weakness on initial examination.

Organophosphates, commonly used in insecticides, inhibit the enzyme cholinesterase, resulting in accumulation of acetylcholine at neurosynaptic junctions. The symptoms of organophosphate poisoning are those of cholinergic toxicity, including blurred vision, weakness, vomiting, diarrhea, cramps, sweating, increased secretions, incoordination, twitching, ataxia, mental status changes, and, if severe enough, respiratory failure and death [87,88]. Respiratory muscle paralysis combines with respiratory center depression, excessive secretions, and, possibly, bronchoconstriction to cause respiratory failure [87,88] (see Chapter 120). Neuralgic amyotrophy, a disorder of the peripheral nervous system affecting the brachial plexus, is associated with diaphragmatic dysfunction and dyspnea [68]. It usually presents with acute severe shoulder pain that may extend to the neck, back, and arm. Motor weakness of the ipsilateral shoulder and arm usually develops within 1 month of the onset of pain. A sensory defect may be present in one-fourth of patients. In one study [68], 12 of 16 patients had bilateral diaphragm paralysis, and 4 of 16 had unilateral diaphragm paralysis. Mild nocturnal desaturation, hypopneas, and obstructive sleep apneas (OSAs) were found in some patients, but alveolar hypoventilation was not found.

**Respiratory Muscle Dysfunction**

A number of systemic myopathies feature prominent respiratory muscle involvement, including the muscular dystrophies, myotonic disorders, inflammatory myopathies, periodic paralyses, metabolic storage diseases, endocrine myopathies, infectious myopathies, toxic myopathies, rhabdomyolysis, and electrolyte disturbances (Table 165.3) [16,25,82,83,96–126].

Generally, the clinical presentation is widespread skeletal muscle weakness. Muscle weakness is the inability of a muscle to generate the
normal expected level of force and should be distinguished from muscle fatigue, which is the inability to generate the preexistent maximum force prior to putting the muscle under load or stress. Fatigue is reversible with rest; weakness may be reversible with reconditioning or the reversal or elimination of the causative factor (e.g., malnutrition, disuse atrophy). Respiratory muscle involvement and respiratory failure usually develop as the disease progresses. On occasion, however, respiratory failure may be the presenting manifestation of a generalized myopathy [97].

Myopathy-induced hypercapnic respiratory failure is almost invariably accompanied by a severely impaired cough mechanism and an inability to clear respiratory tract secretions [5]. Typical pulmonary function findings of respiratory muscle weakness are a decrease in maximum inspiratory and expiratory pressures and, as the disease progresses, a decrease in lung volumes [127].

The muscular dystrophies are inherited disorders that present with evidence of progressive proximal muscle weakness and atrophy [25,101]. Duchenne and Becker muscular dystrophies are caused by mutations in the dystrophin gene, located on the X chromosome [102]. Duchenne dystrophy usually presents at approximately 2 to 3 years of age and Becker dystrophy at approximately 15 to 20 years of age. The limb-girdle muscular dystrophies are a more heterogeneous group of disorders that show both autosomal recessive and autosomal dominant inheritance and include mutations in different members of the sarcoglycan complex, including motilin, dysferlin, caveolin, and sarcoglycan. Myofibrillar myopathy is also associated with mutations in the motilin gene, and both of these may eventuate in respiratory failure [103]. The limb-girdle muscular dystrophies frequently present later in adulthood than do the dystrophin-related muscular dystrophies [104]. The myotonic dystrophies are autosomal dominant disorders linked to two chromosome loci: 19q13, where a CTG repeat has been found in the intron of a serine threonine protein kinase gene, and 3q21, where a CCTG repeat has been found in the intron of zinc finger protein 9 [106,107]. The most prominent clinical features are myotonia (i.e., sustained contraction of muscles in response to direct stimulation), ptosis, prominent distal and facial muscle weakness, and atrophy [25,106,108].

The periodic paralyses are genetic disorders characterized by attacks of muscle weakness in response to a variety of precipitating factors such as exercise, emotional upset, exposure to cold, and, in some cases, exposure to alcohol [25]. Patients may exhibit hypokalemia, hyperkalemia, or normokalemia. In some patients, the disease is unmasked when they become hyperthyroid.

Glycogen storage diseases result from defects in muscle glycogenolysis or glycogen storage. Examples include α-glucosidase deficiency (also called acid maltase deficiency or glycogen storage disease type II) and
muscle phosphorylase deficiency (also called McArdle’s disease or glycogen storage disease type V). Patients exhibit exercise-induced muscle cramping and slowly progressive muscle weakness, with or without atrophy [25,97,98,111]. On occasion, respiratory failure may be the presenting manifestation [97,111]. The diagnosis is confirmed by muscle biopsy and chemical assay for muscle α-glucosidase or phosphorylase level [97,98].

Polymyositis and dermatomyositis are collagen vascular diseases that cause skeletal muscle inflammation. Proximal muscle weakness is prominent and usually develops over a period of weeks to months. Patients may have difficulty swallowing secondary to pharyngeal muscle involvement. Serum muscle enzyme levels are elevated. Typical EMG and muscle biopsy findings confirm the diagnosis [112]. Respiratory muscle failure is an uncommon, but not rare complication of inflammatory myositis [16,112]. Patients with polymyositis may also develop interstitial lung disease, organizing pneumonia, and alveolar hemorrhage [113,114].

Procainamide has been reported to cause a necrotizing myopathy with diaphragm involvement and respiratory failure [126]. Although anti–double-stranded DNA and antihistone antibodies were positive, antinuclear antibodies were absent, and the muscle biopsy did not reveal an inflammatory infiltrate. Neuromuscular junction transmission was normal, suggesting that this was not a drug-induced myasthenic syndrome. Slow improvement in muscle strength followed discontinuation of procainamide in this study.

Increased Impedance to Bulk Flow

In a number of pulmonary disorders, the development of hypercapnic respiratory failure is the result of a marked increase in impedance to ventilation (e.g., increased airflow resistance in COPD or asthma or increased elastic recoil in interstitial fibrosis) that even normal respiratory muscle force generation cannot overcome [3]. It may be less widely appreciated that increases in extrapulmonary impedance to ventilation can also result in hypercapnic respiratory failure. These disorders can be divided into those involving a decrease in chest wall or pleural compliance (e.g., kyphoscoliosis or pleural fibrosis) and those
involving an increase in airflow resistance, resulting from upper airway obstruction (e.g., tracheal stenosis or laryngeal edema) (Table 165.4) [5,42,43,128–189].

Chest Wall and Pleural Disorders

Kyphoscoliosis is a common cause of extrapulmonary respiratory failure [5]. The severity of the scoliosis (i.e., lateral curvature of the spine) is usually the more important factor in the development of respiratory failure than is the kyphosis (i.e., dorsal curvature of the spine) [5]. In idiopathic kyphoscoliosis, chronic hypercapnic respiratory failure generally occurs when the angle of curvature is 120 degrees or greater [5]. In contrast, in paralytic kyphoscoliosis (e.g., as a result of poliomyelitis), the angle of curvature does not reliably predict either vital capacity or hypercapnic respiratory failure [128]. This appears to be owing to a greater element of muscle weakness in paralytic kyphoscoliosis [128]. Even in idiopathic kyphoscoliosis, however, the presence of markedly decreased chest wall compliance is further complicated by inspiratory muscle weakness [129] that contributes to the development of hypercapnic respiratory failure [94]. In addition, a modest element of pulmonary gas exchange abnormality is usually present [5].

Patients with kyphoscoliosis usually report progressive dyspnea on exertion and exercise limitation for a period of years before actual arterial hypercapnia develops [5]. In patients with moderately advanced kyphoscoliosis, acute hypercapnic respiratory failure may result from acute reversible complications such as pulmonary congestion, retained secretions, or pulmonary infection [130].

Massive chest wall obesity may be associated with significant hypoventilation and the development of hypercapnic respiratory failure [133]. This is termed the obesity-hypoventilation syndrome. The pathogenesis of respiratory failure appear to be multifactorial and include significant reduction in chest wall compliance, decreased respiratory muscle efficiency, reduced or blunted respiratory center drive, and impaired pulmonary gas exchange as a result of pulmonary congestion [133–135].

Upper Airway Obstruction

A variety of causes of upper airway obstruction involving the extrathoracic upper airway or intrathoracic trachea can result in the development of respiratory failure (Table 165.4).

Significant upper airway obstruction should be considered in the patient who reports dyspnea in association with inspiratory stridor (extrathoracic obstruction) or expiratory wheezing (intrathoracic obstruction), particularly if other symptoms suggest an upper airway
process (e.g., dysphagia or dysphonia). Unless the patient is acutely ill, the diagnosis is usually evaluated by obtaining a flow–volume loop [190]. This technique not only demonstrates the presence of an upper airway obstruction but usually also helps determine whether it is extrathoracic or intrathoracic and variable or fixed [190]. Studies such as soft tissue neck radiographs, laryngoscopy, and bronchoscopy can identify the exact nature of the structural abnormality.

Upper airway obstruction from bilateral vocal cord paresis or paralysis may result from a variety of causes. The most common cause is trauma, particularly related to thyroid surgery [161] and, occasionally, after endotracheal intubation [162]. Other causes include tumors [142,166–170], cricoarytenoid arthritis [160], herpes simplex viral infection [163], and neurologic conditions, including Guillain–Barré’s syndrome [160], extrapyramidal disorders such as Parkinson’s disease [164], and myasthenia gravis [159]. Bilateral vocal cord paralysis should be considered when one of these conditions is present and the patient reports aspiration, dyspnea, or stridor [161]. Hoarseness is usually absent during normal speech in bilateral adductor paralysis. The results of flow–volume loop analysis can help confirm the presence of the typical extrathoracic variable obstruction associated with bilateral vocal cord paralysis [165].

OSA is increasingly recognized as a cause of intermittent functional upper airway obstruction [3,175,176]. Although obesity is a significant risk factor, OSA can occur in its absence [175,176]. Episodic loss of pharyngeal muscle tone caused by decreased respiratory center motor output, usually during rapid eye movement sleep, results in intermittent airway obstruction [175,177]. This disturbance in respiratory center control also accounts for the mixed apneas (i.e., combination obstructive and central apneas) frequently seen in these patients [175,177].

Approximately 10% to 20% of patients with OSA have chronic alveolar hypoventilation with elevation in PaCO₂ even while awake. These patients frequently have concomitant COPD or morbid obesity. Hypoxemia, whether just at night or all day, eventually causes cardiac arrhythmias, pulmonary hypertension, and cor pulmonale [3,175,178,179].

The diagnosis of OSA can be established by a sleep study (polysomnography) [174,175]. Other conditions that can cause or exacerbate OSA should be excluded, including adenotonsillar hypertrophy [180]; deviated nasal septum [176]; retrognathia or micrognathia [3]; macroglossia from acromegaly [183]; endocrine and metabolic abnormalities such as hypothyroidism [67,184,185]; CNS depression from ethanol, barbiturates, and benzodiazepines [175,186]; and exogenous androgen administration [187,188] (see Chapter 183).
DIFFERENTIAL DIAGNOSIS

The major differential diagnosis of extrapulmonary respiratory failure is hypercapnic respiratory failure from intrinsic lung diseases (e.g., COPD) (Fig. 165.1). These conditions, usually, can be readily distinguished because they are almost always associated with a markedly elevated P(A–a)O₂ gradient when calculated on room air, thus reflecting a severe derangement of distal gas exchange. Hypercapnic respiratory failure may also result from a combination of pulmonary and extrapulmonary abnormalities. This combined diagnosis is suggested by a P(A–a)O₂ gradient in the range of 25 to 30 mm Hg. If the extrapulmonary abnormality is predominant, the gradient, although abnormal, is generally less than 25 mm Hg [5]. When primary pulmonary disease is severe enough to cause hypercapnia, the gradient is generally above 30 mm Hg.
TREATMENT

The treatment of extrapulmonary respiratory failure can be divided into specific and supportive therapy. Supportive therapy involves the use of noninvasive or invasive mechanical ventilatory assistance (see Chapters 166 and 167), supplemental oxygen, and techniques of airway hygiene (see Chapter 169). In addition, regardless of the primary cause of respiratory muscle weakness, malnutrition exacerbates it and nutritional replacement can increase respiratory muscle strength and function [191,192]. In selected circumstances, inspiratory resistive training of the respiratory muscles and the use of theophylline as a positive respiratory muscle inotrope have been reported to improve respiratory muscle function and associated hypercapnic respiratory failure [193–196]. Only specific forms of therapy are discussed here and in Tables 165.1 through 165.4.

Central Nervous System Depression

A description of specific treatment modalities for CNS depression is given in Table 165.1.

Peripheral Nervous System Dysfunction

Treatment for peripheral nervous system disorders is outlined in Table 165.2. In general, there is little in the way of specific therapy for established spinal cord or anterior horn cell disease. The use of phrenic nerve pacemakers for high-level cervical cord transection may help treat the resultant respiratory failure when nerve conduction studies have determined that the phrenic nerves are intact and functioning [48–50,91]. If pacing brings on OSA, noninvasive positive airway pressure or tracheostomy may be necessary.

The availability and value of specific therapy for peripheral neuropathy depend on the cause. In the case of acute Guillain–Barré’s syndrome, plasma exchange or intravenous infusion of pooled γ-globulin may be helpful when administered promptly for patients who reach or appear to be approaching the inability to walk without help or who have substantial decrease in ventilatory capacity or bulbar insufficiency (for more details on treating Guillain–Barré’s syndrome, see Chapter 152).

Patients with severe respiratory muscle weakness because of Guillain–Barré’s syndrome require supportive mechanical ventilatory assistance, usually for weeks to months [59]. If cranial nerve involvement is prominent and the patient is unable to swallow or clear oral secretions,
Intubation for airway protection should be considered, even in the absence of overt respiratory failure. Management is often complicated by autonomic nervous system dysfunction, which is a leading cause of death in this syndrome [90]. Characteristic abnormalities of increased or decreased sympathetic and parasympathetic nervous systems activity include hypertension, hypotension, bradyarrhythmias, tachyarrhythmias, flushing, diaphoresis, and ileus [90]. Because these events are often transient, minor fluctuations in heart rate or blood pressure should not be treated. When intervention is deemed necessary, short-acting and easily titratable drugs should be used [90]. Because patients are at increased risk for deep venous thrombosis and pulmonary embolism, prophylactic anticoagulation should be administered, according to guidelines for critically ill patients (for more details on anticoagulation in critically ill patients, see Chapter 93). Treatment of respiratory failure caused by myasthenia gravis is directed primarily at the myasthenia (see Chapter 153).

Drug-induced neuromuscular blockade often improves simply by discontinuing the offending agent [57]. Intravenous calcium gluconate may help to shorten the recovery time by reversing the presynaptic component of the neuromuscular blockade [76]. If this fails and the patient improves after an edrophonium chloride test, neostigmine bromide may be effective by reversing the postsynaptic component [52]. When myasthenia gravis is exacerbated or made manifest by a drug, therapy directed specifically at the myasthenic symptoms may be required [76].

Treatment of botulism is directed at minimizing further binding of toxin to nerve endings while supporting the patient until bound toxin dissipates [85] (see Chapter 86). Recovery of ventilatory and upper airway muscle strength in type A botulism occurs slowly; patients recover most of their strength in the first 12 weeks, but full recovery may take up to a year [86].

**Respiratory Muscle Dysfunction**

The treatment of myopathy depends on the cause (Table 165.3). Although the mechanism is not known, glucocorticoid therapy has resulted in some improvement in muscle strength in Duchenne muscular dystrophy, but adverse effects need to be monitored closely [102,105].Mexiletine may be helpful in myotonic dystrophy, but is contraindicated in patients with heart block; other antiarrhythmic and anticonvulsive agents may also be of benefit [109]. These agents as well as sodium channel blockers can also worsen weakness while relieving myotonia.

Some patients with each of the different subtypes of periodic paralysis have responded well to acetazolamide, a carbonic anhydrase inhibitor
that is kaliuretic [110]. Acetazolamide is often dramatically effective in preventing acute attacks of hypokalemic periodic paralysis, perhaps by causing a metabolic acidosis that, in turn, protects against the sudden decreases in potassium that provoke attacks. Certain patients benefit from low-carbohydrate or low-sodium diets in addition to acetazolamide. Inhalation of the β-adrenergic agonist albuterol alleviates acute attacks of weakness in some patients with hyperkalemic periodic paralysis [110].

Polymyositis-induced muscle weakness often responds to glucocorticoids or other immunosuppressants [112,114]. Muscle weakness from hypothyroidism, hypophosphatemia, hypomagnesemia, or hypokalemia responds to replacement therapy [25,115,116,119,121,122].

The specific treatment of trichinosis is less than satisfactory [118]. For patients with severe infection, albendazole or mebendazole together with systemic glucocorticoids may shorten the duration of myositis and muscle pain [118]. Albendazole is preferred over mebendazole owing to more consistent blood levels. The other mainstays of treatment are bed rest and anti-inflammatory analgesic agents.

Chest Wall and Pleural Disorders

Treatment for chest wall and pleural disorders is largely supportive (Table 165.4). If acute respiratory failure develops in kyphoscoliosis, reversible factors such as pulmonary congestion, infection, retained secretions, and other intercurrent illnesses should be sought and treated [130]. Episodes of acute respiratory failure in patients with kyphoscoliosis can often be managed with noninvasive positive-pressure ventilation (for details of noninvasive ventilation for acute respiratory failure, see Chapter 167).

When severe kyphoscoliosis is associated with significant chronic hypercapnic respiratory failure, nocturnal noninvasive positive-pressure ventilation often results in marked improvement in daytime function and gas exchange [131,197].

Upper Airway Obstruction

The first step in treating acute upper airway obstruction is to establish an adequate airway. Specific definitive therapy can then be used. In acute bacterial epiglottitis associated with significant respiratory distress, immediate steps are mandatory to prevent development of total obstruction [140]. Chapters 8, 9, 169, and 180 provide a complete discussion of this and other treatment issues.
Treatment of OSA is indicated when significant sleep-related apneas or hypopneas are noted in the setting of signs and symptoms such as morning headaches, daytime functional impairment, peripheral edema, cor pulmonale, and elevated hematocrit. In general, nasal continuous or bilevel positive-pressure devices (continuous positive airway pressure or bilevel continuous positive airway pressure) are effective [198–200] (see Chapters 169 and 183). In OSA complicated by life-threatening arrhythmias, severe arterial hypoxemia, or severe functional impairment [3,176], tracheostomy may rarely be necessary [3,42,176]. Other treatment modalities for OSA include weight loss [201], avoidance of alcohol and sedative drugs [175,186], mandibular and tongue repositioning appliances [202], and upper airway surgery other than tracheostomy (uvulopalatopharyngoplasty, tonsillectomy, adenoidectomy, and deviated septum repair), as appropriate [180,203]. When an identifiable cause of OSA is present (e.g., hypothyroidism), correction of the problem may be curative [184,185].

A summary of advances in the treatment of extrapulmonary respiratory failure is presented in Table 165.5.

INTRODUCTION

Invasive mechanical ventilation (MV) describes controlled or assisted ventilation through an endotracheal tube, tracheostomy, or (rarely) esophageal obturator airway. Noninvasive ventilation is described in Chapter 167. This chapter describes ventilator modes, interpretation of respiratory system mechanical properties using pressure and flow waveforms, indications for MV and extracorporeal life support (ECLS), a patient-centered approach to ventilator settings, complications of MV, and the role for ECLS for patients with cardiopulmonary failure.

MV is used when the patient’s spontaneous breathing is insufficient to sustain life, when it is useful to take control of respiration because of impending failure of other systems, or to support patients through deep sedation or therapeutic paralysis. Intensive care unit (ICU) ventilators operate by applying supra-atmospheric pressure to the invasive airway appliance, driving bulk gas flow along a pressure gradient into the alveoli (inspiration) and (usually) allowing passive expiration.
MODES OF MECHANICAL VENTILATION

Physiology of Positive Pressure Ventilation

Initial ventilator modes were designed to deliver breaths of air mixed with oxygen at a fixed volume (tidal volume, $V_T$) and frequency (controlled modes). These modes did not take into consideration the patient’s effort, and consequently they were often associated with significant ventilator dyssynchrony, requiring deep levels of sedation and paralysis. Subsequently, new ventilator modes were developed that had the capacity to sense the patient’s inspiratory effort, improving synchrony of breath onset and termination (assisted modes). Despite this progress, the general prevalence of ventilator dyssynchrony among mechanically ventilated patients (discussed in detail below) is still estimated at up to 25%, with higher values in specific populations like COPD and children. Lately, complex ventilator modes have been developed seeking to improve patient–ventilator synchrony; respond more readily to changing conditions; and adjust settings without clinician intervention.

In order to understand ventilator modes, it is essential to first describe the key components of individual breaths, characterized by (a) how the breath is initiated (trigger); (b) what governs gas flow during the breath (target); and (c) how the breath is terminated (cycle) (see Table 166.1). Ventilator modes are created based on which breath types are delivered and whether spontaneous breaths (SB) are allowed (Table 166.2).

Effort describes triggering through pressure, flow, or the diaphragm electromyographic signal.

| TABLE 166.2 Common Ventilator Modes are Composed of Breath Types |
### Defining Characteristics of Breath Types

#### Trigger

MV breaths are triggered in one of four possible ways: (a) time, (b) pressure, (c) flow, or (d) neural sensing. Time is the trigger for controlled breaths, meaning that a breath will be delivered after a fixed time from the prior breath, defined by the set respiratory rate (time = 60 per frequency). In contrast, assisted breaths rely on the ventilator to detect patient effort. Most commonly, effort is sensed through a fall in pressure at the airway opening (pressure trigger) or by detecting a difference in the bias flow comparing the inspiratory and expiratory limbs of the ventilator circuit (flow triggering). In the majority of ventilated patients the means of effort detection has no significant impact on the efficiency of triggering or work of breathing, and is selected based on physician preference. However, in some clinical scenarios (such as in the presence of an air leak, for example when a bronchopleural fistula is present), choice of trigger can be important, because relying on flow can produce auto-triggering, a form of ventilator dyssynchrony. Neural sensing, in which the integrated diaphragmatic electromyographic signal is used to initiate the breath, improves neuroventilatory coupling \[1\], especially for patients with severe airway obstruction and in children.

#### Target

Ventilator breaths are conventionally classified based on the targeted
variable: pressure-targeted breaths versus flow-targeted breaths. For pressure-targeted breaths, the clinician sets and the ventilator produces a controlled pressure ($P_I$) throughout inspiration. Generally, $P_I$ is constant although it can vary during proportional-assist breaths or those based on the diaphragm EMG. In contrast, during flow-targeted breaths, the clinician sets and the ventilator delivers a controlled inspiratory flow rate ($V \cdot I$). Generally, $V \cdot I$ is constant throughout the breath (constant flow or square wave), but can also decelerate or vary sinusoidally. Although clinicians tend to think of pressure- and flow-targeted breaths as differing fundamentally, in fact they are tightly coupled through the equation of motion for the respiratory system. This equation relates pressure at the airway opening ($P_{ao}$), volume above FRC ($V$), compliance of the respiratory system ($C_{RS}$), inspiratory flow ($V \cdot I$), respiratory system resistance ($R$), flow acceleration ($V \cdot .. I$), inertance ($I$), and the pressure produced by the inspiratory muscles ($P_{mus}$) as follows:

$$P_{ao} = V \cdot C_{RS} + V \cdot I \cdot R + V \cdot .. I - P_{mus}$$

According to this physiologic relationship, during pressure-targeted breaths ($P_{ao}$ is generally constant and thus is the independent variable), volume and flow depend on $P_{ao}$ along with $C_{RS}$, $R$, and $P_{mus}$ (the inertance term is only relevant when there are rapid changes in flow, as during high frequency ventilation). Similarly, during flow-targeted breaths ($V \cdot I$ is generally constant and is the independent variable), $P_{ao}$ becomes the dependent variable (Fig. 166.1). These points are crucial for two reasons: (1) the ventilatory impact of pressure- and flow-targeted breaths are linked by the mechanical properties of the respiratory system (in the passive patient these include only $C_{RS}$ and $R$); and (2) this equation forms the basis for deriving clinically important information about the respiratory system from pressure and flow waveforms, as discussed further below.
Some unusual ventilator modes allow dual-control breaths, in which both pressure and flow can be targeted within a single breath. For example, “volume-assured pressure support” breaths begin as typical PS breaths but, if the projected tidal volume falls below the target, the breath switches to an AC, flow-targeted breath until completion. There are no apparent advantages to such dual-control breaths and modes.

**Cycle**

The cycle variable is the factor that terminates inspiration. There are four possible cycle variables: (a) time; (b) flow; (c) volume; (d) neural sensing. PC breaths are terminated by time (inspiratory time, $T_I$), often set between 0.5 and 1.0 seconds. At any given rate, inspiratory time determines expiratory time (because the number of seconds in each breath cycle = 60/frequency), so there are important consequences to the time chosen, especially in patients with airflow obstruction. Flow is the cycle variable for PS breaths, which terminate when flow falls to a specified fraction of the initial inspiratory flow or, on some ventilators, below an absolute threshold of flow. Because $P_{ao}$ is (usually) constant during pressure-targeted breaths, $V_I$ tends to decelerate throughout the breath as lung volume and lung recoil rise and effort falls, according to the equation of motion. Often, a value near 30% of initial flow is chosen to signal the ventilator to switch off because, in normal subjects, this tends to coincide with cessation of inspiratory effort (i.e., ventilator $T_I$ approximates neural $T_I$, enhancing synchrony). The rate of fall of the flow depends on the mechanical properties of the respiratory system [2], however; for patients with severe airflow obstruction, this can lead to very long ventilator $T_I$ (longer than neural $T_I$) and patient–ventilator dyssynchrony [3]. For these patients, synchrony can be improved by raising the cycle threshold to 50% or even higher.

The third means to cycle from inspiration to expiration is to rely on delivered volume, typical of flow-targeted breaths. When flow is constant, this is analogous to using time to cycle the breath, because $V = V_I \times \text{time}$.
time. Finally, inspiration can be cycled off by using the declining signal from the diaphragm EMG. Regardless of the target, all ventilators have an additional maximal pressure limit as a safety feature to prevent lung overpressurization. This pressure is set by the clinician, often 10 cm H$_2$O above the peak pressure; whenever this pressure is exceeded, the ventilator sets off an alarm and opens the expiratory valve to release the rest of the breath to the atmosphere.

**Ventilator Modes**

Ventilator modes are created based on which types of breaths are included, and whether spontaneous breathing is allowed. The profusion of modes can be confusing and is often driven by marketing imperatives and untested theories about what might confer benefits for critically ill patients. The evidence base supporting advantages for any particular mode is scant [4,5]. For each mode below, we describe the component breaths, settings the clinician must choose, and impact of patient effort. Positive end-expiratory pressure (PEEP) is discussed separately.

**Volume Assist Control Ventilation**

Volume assist control mode allows both VC and VA breaths, so is time- or effort-triggered, flow-targeted, and volume-cycled. In this mode the physician sets the tidal volume, inspiratory flow rate, and respiratory frequency. The I:E ratio, $T_I$, and the expiratory time ($T_E$) are determined by the combination of inspiratory flow rate, tidal volume, and frequency. At constant tidal volume, the higher the inspiratory flow rate, the shorter the $T_I$ and the smaller the I:E ratio (Fig. 166.2).
As in most flow-targeted modes, flow remains constant and volume rises linearly throughout inspiration, while pressure is determined by the respiratory system mechanical properties. The figure represents a passively ventilated patient; the $V_T$, $T_I$, and RR set by the clinician determine the I:E ratio and flow rate. If the patient triggers an extra breath, then the same tidal volume would be delivered at the same flow rate and $T_I$, but the I:E ratio would change.

In the passively ventilated patient a set tidal volume is delivered with each VC breath at a specified frequency. In the actively breathing patient, extra breaths can be triggered (VA), each at the same $V_T$ and inspiratory flow rate as VC breaths: this will change the I:E ratio and $T_E$. When respiratory drive is high, or when neural $T_I$ exceeds the ventilator $T_I$, patients may trigger a second breath (rarely a third) which is superimposed on the initial breath. This phenomenon, called double-triggering, is especially common during lung-protective ventilation of the acute respiratory distress syndrome (ARDS), and risks overdistention of lung or dynamic hyperinflation [6].

**Volume-Synchronized Intermittent Mandatory Ventilation**

Volume-synchronized intermittent mandatory ventilation (V-SIMV) entails VC, VA, PS, and SB, so is time- or effort triggered; flow- or pressure-targeted; and time- or flow-cycled. In the passive patient, it behaves the same way as volume assist control ventilation (VACV). In actively breathing patients, if the triggering effort occurs close to the next
scheduled mandatory breath (defined interval or synchronization window), the ventilator delivers a VA breath and resets the interval until the next time-cycled breath. If the triggering effort occurs before the synchronization window, a PS or spontaneous breath follows (unsynchronized breath) (Fig. 166.3).

**FIGURE 166.3** Volume-synchronized, intermittent, mandatory ventilation (V-SIMV). The different breath types delivered by V-SIMV mode in an actively breathing patient are shown: controlled breath (VC), followed by two unsynchronized spontaneous breaths (SB) and a synchronized-assisted breath (VA). Notice that the VA breath is composed of the same flow rate and volume as the VC breath but pressures are lower in accord with the patient’s inspiratory effort. Here, the unsynchronized breaths are SBs, but these can also be pressure support breaths.

This ventilator mode has been used traditionally as a weaning strategy, although its use is decreasing, perhaps because it appears to prolong ventilator liberation.

**Pressure Assist Control Ventilation**

This mode consists of both pressure assist (PA) and PC breaths (time- or effort-triggered, pressure-targeted, and time-cycled). The respiratory rate (f), P_I, and T_I are set by the clinician, whereas the inspiratory to expiratory (I:E) ratio is determined indirectly based on f and T_I. With every breath, pressure rises quickly to the P_I, although a “rise time” can
be set to slow the rate of rise. Most often the rise time is 0 during invasive ventilation, although a brief (0.1 to 0.2 second) rise time can aid synchrony in some patients (Fig. 166.4).

**FIGURE 166.4** Pressure assist-control ventilation. Pressure is constant throughout inspiration, within the limits of the ventilator to control it. The inspiratory flow falls throughout the breath as the alveolar pressure rises. In this patient, the first breath is controlled (PC) while the next three are assisted (PA). The downward deflection of the pressure curve at the beginning of inspiration (PA breaths) represents the patient’s inspiratory effort triggering the breath (arrow). Note the subtle differences in inspiratory flow during the PA breaths related to variable patient effort.

For the passive patient without airway obstruction and sufficiently long inspiratory time, \( P_I \) and alveolar pressure \( (P_{alv}) \) equilibrate at end inspiration (signaled by zero flow), and the tidal volume is predictable \( (V_T = C_{RS} \times [P_I - PEEP]) \). For patients with airflow obstruction or short \( T_I \), there will not be equilibration between \( P_I \) and the alveolar pressure, flow does not fall to zero at end-inspiration, and \( V_T \) will be smaller than that predicted based on \( C_{RS} \) and \( P_I \). For a patient who is actively breathing, \( V_T \) is often augmented by effort, and is usually larger than predicted by \( C_{RS} \) and \( P_I \). In addition, active patients can trigger additional breaths increasing minute ventilation, reducing expiratory time \( (T_E) \), and increasing the I:E ratio.
Pressure Support Ventilation

Pressure support breaths (effort-triggered, pressure-targeted, and flow-cycled) comprise this mode. The patient must trigger the ventilator to deliver a breath, so this mode cannot be applied to passive patients. The clinician sets $P_I$ and (optionally) the flow threshold for cycling the breath off: rate and minute ventilation depend on the patient’s drive (Fig. 166.5). For patients with periodic breathing (relatively common in the critically ill), pressure support ventilation (PSV) can amplify the hyperpneic periods and extend the duration of apneas, especially when $P_I$ is set to high levels. If this causes alarms to sound, reducing the level of $P_I$ usually shortens or abolishes apneas.

![Image of pressure support](image)

**FIGURE 166.5** Pressure support. As is typical of most pressure-targeted modes, the inspiratory flow falls throughout the breath as the alveolar pressure rises (because of elastic recoil and falling inspiratory effort). Appreciate how tidal volume and inspiratory flow rate are determined, in part, by the patient’s respiratory effort that can vary from breath to breath, while the $P_{ao}$ is maintained constant ($P_I + PEEP$).

Pressure SIMV

The combination of PC, PA, PS, and SB makes up pressure SIMV (Fig. 166.6). The clinician sets rate, $P_I$ (PC and PA breath-related $P_I$ is set independently of the $P_I$ for PS breaths), and $T_I$. This mode is therefore effort- or time-triggered; pressure-targeted; and both time-cycled (PC and PA breaths) and flow-cycled (PS breaths). When the patient is
passive, pressure SIMV becomes simply pressure control mode. When
the patient triggers a breath in a brief window before a planned time-
cycled PC breath, the breath becomes a PA breath. If patient effort
precedes this window, the breath is instead PS or SB (depending on
whether the clinician has enabled PS breaths). SIMV was created with the
hope that it would ease the transition between full ventilatory support
and spontaneous breathing, but instead IMV seems to impede weaning
[7,8].

**FIGURE 166.6** Pressure-synchronized,
intermittent, mandatory ventilation (SIMV). Similar to
volume-SIMV, several breath types can be delivered by
this mode in an actively breathing patient: a controlled
breath (PC) is followed by two unsynchronized
spontaneous breaths (SB) and a synchronized assisted
breath (PA). PA breaths have the same pressure profile
and $T_I$ as PC breaths. For unsynchronized breaths,
pressure support is set at zero.

**Pressure-Regulated Volume Control and Volume
Support Ventilation**

Although the name pressure-regulated volume control (PRVC) suggests
that it targets flow (or volume), in fact PRVC is a pressure-targeted mode
allowing only PC and PA breaths (Fig. 166.7). In this mode the clinician
sets an initial $P_I$, $T_I$, frequency, and a tidal volume goal. The ventilator
automatically and continually adjusts $P_I$ to achieve the desired $V_T$.
Therefore, if respiratory system mechanical properties or patient effort
changes, so will $P_I$. This is one means of controlling tidal volume for
patients with ARDS although, compared with VACV, it may increase the
work of breathing [9]. No patient-centered benefits have been described [5]. A similar mode is volume support ventilation (VSV) which uses PS breaths also to achieve a target tidal volume. Because it uses PS rather than PC and PA breaths, VSV differs from PRVC in that T₁ and frequency are not controlled by the clinician.

![Pressure-regulated volume control](image)

**FIGURE 166.7** Pressure-regulated volume control. In this passively ventilated patient, the clinician switched the target Vₜ from 800 to 500 mL. Appreciate how the Pᵢ is adjusted by the ventilator and decreases gradually to deliver the new target Vₜ. The time axis has been compressed for illustration purposes.

### Airway Pressure Release Ventilation

PC, PS, and SB are combined during airway pressure release ventilation (APRV), making it time- and effort-triggered, pressure-targeted, and time- and flow-cycled, but this mode is characterized especially by a very long T₁ (Fig. 166.8). This same mode is sometimes referred to as biphasic positive airway pressure, especially in Europe, and has also been termed “upside-down SIMV.” The clinician enters frequency, T_LOW (which is simply Tₑ), P_HIGH (Pᵢ), and P_LOW (PEEP). T_LOW is kept brief in order to produce auto-PEEP (autoPEEP), but there is no agreement as to how this should be done. Some users of APRV advocate setting T_LOW according to the expiratory flow curve; others base it on the expiratory time constant of the respiratory system. T_HIGH (Tᵢ) is determined mathematically as a consequence of T_LOW and frequency (generally about 10 breaths/min).
$P_{\text{HIGH}}$ is often set below the upper inflection point of the pressure–volume (PV) curve or near the plateau airway pressure determined during VACV breaths. $P_{\text{LOW}}$ can be set at zero, adjusted based on oxygenation, titrated to be just above the lower inflection point of the PV curve, or raised until $V_T$ falls to 6 mL/kg predicted body weight.

![Airway pressure release ventilation](image)

**FIGURE 166.8** Airway pressure release ventilation in an actively breathing patient. The $P_{\text{HIGH}}$ represents the $P_{I}$, and $P_{\text{LOW}}$ the PEEP, while $T_{\text{LOW}}$ represents the $T_E$, and $T_{\text{HIGH}}$ the $T_I$. The patient can trigger spontaneous breaths (SB or pressure support) in combination with this mode during $T_{\text{HIGH}}$ or $T_{\text{LOW}}$. $T_{\text{LOW}}$ is typically quite short in order to produce autoPEEP (note that expiratory flow does not cease at the end of $T_{\text{LOW}}$).

In the absence of spontaneous respiratory efforts, APRV is identical to pressure assist-control ventilation (PACV) (albeit with inspiratory and expiratory times inverted—this is a form of inverse ratio ventilation). The point of APRV, however, is to facilitate spontaneous breathing. This mode allows unrestricted spontaneous ventilation throughout the respiratory cycle, both during $T_{\text{HIGH}}$ and $T_{\text{LOW}}$, and these can be PS or SB. This mode was created as a more comfortable means for delivering inverse ratio ventilation and is often used in severe ARDS. There are three downsides to APRV: (a) tidal volume often exceeds values thought
to be lung-protective; (b) derecruitment during $T_{\text{LOW}}$ could produce atelectrauma; and (c) spontaneous breathing in early, severe ARDS may worsen outcomes [10]. Clinical trials have shown no patient-centered advantages to this mode [11–13].

**High Frequency Oscillatory Ventilation**

High frequency oscillatory ventilation (HFOV) is an alternative mode of ventilation in which the mean airway pressure ($P_{aw}$) is held constant while an oscillating pump delivers small tidal volumes at a rapid rate. HFOV has drawn interest in the management of ARDS for two reasons. First, it could be lung-protective by virtue of maintaining high $P_{aw}$ (to keep the lungs open) while superimposing only very small tidal swings (to keep driving pressure and tidal volumes small). Second, the high $P_{aw}$ characteristic of HFOV has the potential to recruit lung alveolar units when PEEP is ineffective, thereby treating refractory hypoxemia.

In HFOV, the clinician sets: $P_{aw}$, amplitude of the oscillatory pressure, frequency (Hz), bias flow, $FiO_2$, and inspiratory time. $P_{aw}$ is the primary setting that regulates lung volume and alveolar recruitment so that, in conjunction with $FiO_2$, it exerts the most control over oxygenation.

Amplitude determines the displacement of the piston in the ventilator; this displacement impacts the volume delivered to the patient (the “oscillatory volume”). Empirically, the $PaCO_2$ level correlates inversely with the product of the frequency and the square of the oscillatory volume. Because oscillatory volume (unlike tidal volume during conventional ventilation) is a complex function of amplitude, frequency, and duty cycle, the impact of ventilator changes on gas exchange is not self-evident. For example, reducing frequency tends to lower the $PaCO_2$ because oscillatory volume rises as a consequence, and this secondary effect has a greater impact on $CO_2$ exchange than the lower respiratory rate.

Two large, prospective, randomized trials compared HFOV to conventional lung-protective ventilation in adults [14,15]. In the first (OSCAR, Oscillation in ARDS) [14], 795 patients were randomized to HFOV (initial settings were $P_{aw}$ 5 cm H$_2$O above the mean airway pressure at enrollment; frequency 10 Hz) or to conventional ventilation (local usual practice, although pressure-assist control ventilation and tidal volume 6 to 8 mL/kg predicted body weight (PBW) were encouraged). There was no difference in all-cause mortality 30 days after randomization (the primary outcome) or length of stay in the ICU or hospital. In the second trial, 548 subjects were randomized to HFOV
(initial $P_{aw}$ 30 cm H$_2$O, adjusted to oxygenation; frequency 3 to 12 Hz) or conventional ventilation (pressure-assist control, tidal volume 6 mL/kg PBW; high PEEP table) [15]. In-hospital mortality was significantly higher for the HFOV group (47% vs. 35%; $p = 0.005$) causing the study to be terminated early.

Based on these trials, HFOV should not be used routinely in adults. However, both of these studies address whether HFOV confers superior lung protection when used in moderate to severe ARDS, and not whether HFOV has a role as a rescue therapy. If HFOV is chosen as rescue therapy for adults with refractory hypoxemia, careful and serial assessment of fluid balance and right ventricular function is recommended.

**Proportional Assist Ventilation**

This mode is a form of PSV, but $P_1$ varies throughout inspiration as a function of patient effort. Thus it is effort-triggered, pressure-targeted, and flow-cycled. Proportional assist ventilation (PAV) was created in response to a fundamental limitation of conventional flow- and pressure-targeted modes: ventilatory assistance is not proportional to patient effort. In contrast, PAV amplifies patient instantaneous effort throughout inspiration, leaving the patient in control of $V_T$, $T_I$, $T_E$, and $V_I$. The theory behind PAV rests on the equation of motion for the respiratory system, as follows:

$$P_{mus} + P_{ao} = V \times E_{RS} + V \times I \times R_{RS}$$

where $P_{mus}$ is the muscular pressure, $P_{ao}$ is the airway opening pressure controlled by PAV, $V$ is volume, $E_{RS}$ is elastance, $V \times I$ is flow, and $R_{RS}$ is resistance. The ventilator monitors instantaneous rate and volume of gas flow from the ventilator, then varies $P_{ao}$ according to two functions: elastic assist and resistive assist. The clinician determines the degree of assistance, usually set at 40% to 80%. PAV matches the patient’s respiratory neural activity very well; and several physiologic studies have suggested better ventilator synchrony with PAV compared to PSV [16–18].

**Neurally Adjusted Ventilatory Assist**

This novel mode provides a pressure targeted breath in proportion to the electrical activity of the diaphragm (EAdi), measured through microelectrodes built into a nasogastric tube and placed at the level of the diaphragmatic crura. Neurally adjusted ventilatory assist (NAVA) is electrically triggered; pressure-targeted; and electrically cycled. The
timing and intensity of ventilatory assist is determined by the timing and intensity of the diaphragmatic electrical activity (Fig. 166.9).

![Diagram of ventilatory assist](image)

**FIGURE 166.9** Neurally adjusted ventilator assist. In this mode, pressure-targeted breaths are delivered in proportion to the electrical activity of the diaphragm (EAdi). The lower part of the panel shows the timing and intensity of the diaphragmatic electrical activity, which determines the timing and intensity of ventilatory assist.

\[
P_{ao} (\text{cm H}_2\text{O}) = \text{NAVA level} (\text{cm H}_2\text{O}/\mu\text{v}) \times \text{EAdi} (\mu\text{v})
\]

The NAVA level is set by the clinician through a titration process of stepwise changes in ventilatory assist. The end of inspiration and opening of the expiratory valve is determined by the EAdi signal reaching 40% to 70% of the peak EAdi. NAVA requires correct positioning of the electrode sensors, normal diaphragmatic anatomy, and intact ventilatory drive and breathing reflexes. The ventilator also has a safety mechanism: it switches to PACV or PSV if EAdi is not detected [19]. NAVA is thought to produce better neuroventilatory coupling than other conventional modes, decreasing the prevalence of ventilator asynchrony, especially for children [20], although the evidence in the adult population is limited [21,22]. A systematic review assessing the effectiveness and safety of NAVA in critically ill patients (adults and children) compared to conventional MV modes is currently underway [23].
Volume Assured Pressure Support

Rapid microprocessors allow ventilators to respond to changing conditions so rapidly that the level of ventilatory support can be changed within a single breath. With volume assured pressure support (VAPS), each breath begins as PS but, if the ventilator calculates that a target tidal volume will not be reached, switches (within that breath) to a VC breath. The clinician sets P<sub>I</sub> and a target V<sub>T</sub>.

Choosing a Ventilatory Mode

For the majority of ventilated patients, the choice of the ventilator mode is based on physician preference, and probably does not impact clinical outcomes. Indeed, a capable clinician can achieve similar degrees of ventilator support using almost any mode. It is likely more important to emphasize the principles of ventilator-induced lung injury (VILI), ventilator-induced diaphragm dysfunction (VIDD), and patient–ventilator dyssynchrony (PVD) than to focus on ventilator modes [4,5]. Nevertheless, there are some advantages and disadvantages of various available modes.

Advantages for Flow-Targeted Modes

One of the greatest benefits of using flow-targeted modes is that the mechanical properties of the respiratory system are readily apparent (as discussed further below). This is especially true when using constant-flow (square wave) ventilation. Another plus is that it is quite simple to limit tidal volume when one desires lung-protective ventilation, despite changing effort, sedation, and respiratory mechanics.

Advantages for Pressure-Targeted Modes

Pressure-targeted modes allow variable flow and some clinicians feel this enhances patient comfort. A second advantage is that when ventilating patients with severe airflow obstruction, pressure-targeted modes offer a built-in degree of protection against runaway dynamic hyperinflation: if autoPEEP rises while P<sub>I</sub> remains constant, the driving pressure falls, lowering minute ventilation and tending to limit hyperinflation.

Positive End-Expiratory Pressure

During expiration, rather than opening the expiratory limb of the ventilator to the atmosphere, a valve is controlled in order to maintain...
positive pressure. This PEEP is used (a) to reduce the risk of atelectasis; (b) recruit alveoli and raise oxygenation in patients with pulmonary edema; (c) lower the inspiratory threshold load of autoPEEP in patients with airflow obstruction; and (d) reduce left ventricle (LV) afterload in patients with reduced systolic function. PEEP has important effects on the cardiovascular system, discussed below.

Reducing Atelectasis

The simple act of inserting an endotracheal tube lowers FRC, increasing the risk of atelectasis. This may be related to “laryngeal braking,” an effect bypassed by the tube. When FRC falls, some lung regions (especially dependent zones) may fall below closing volume, producing resorptive atelectasis. For this reason, nearly all mechanically ventilated patients are given a minimum value of PEEP (usually 5 cm H$_2$O), sometimes referred to as “physiologic PEEP.”

Use in Lung Edema

For patients with ARDS or cardiogenic pulmonary edema, PEEP is often effective for redistributing lung water from the alveolar space to the peribronchial, perivascular cuffs [24], raising FRC, recruiting alveoli, and raising PaO$_2$. Patients vary greatly in their response to PEEP, however, ranging from dramatic increments in oxygenation to little effect to “paradoxically” reduced PaO$_2$. The latter may be seen especially in focal consolidations. There is controversy regarding how to set PEEP in ARDS. Some advocate low levels, such as the least PEEP effective in maintaining adequate oxygenation or according to a low-PEEP table. Others argue that higher levels of PEEP are salutary by inhibiting atelectrauma. Clinical data have not resolved this question. Even if higher levels of PEEP are beneficial, there is no consensus regarding how to choose the level: analysis of PV curves, stress index, esophageal manometry, high-PEEP table, or other methodologies [25–30]. This topic is discussed in greater detail in Chapter 30.

In Obstructive Disease

During exacerbations of obstructive lung disease, the end-expiratory P$_{alv}$ typically remains above atmospheric pressure (autoPEEP). This produces an inspiratory threshold load; that is, the patient has to expend significant effort to overcome autoPEEP even before inspiratory flow can be produced. Applying PEEP extrinsically reduces this load, lowering the work of breathing. Externally applied PEEP tends not to raise P$_{alv}$
because the airways often behave like Starling resistors, rather than Ohmic resistors, analogous to waterfalls [31]. Externally applied PEEP set to roughly 75% of the autoPEEP lowers work of breathing usually without raising the degree of hyperinflation [32,33].

LV Dysfunction

PEEP raises mean and end-expiratory $P_{pl}$, reducing LV transmural pressure as described further below in “Heart–Lung Interaction.” For patients with severe LV dysfunction, this effect is meaningful and can be effective when treating pulmonary edema, reducing mitral regurgitant fraction, and augmenting cardiac output. Withdrawal of PEEP can provoke clinical deterioration or weaning failure. This may be one of the reasons that extubation to noninvasive ventilation reduces the risk of extubation failure for patients with a cardiovascular basis for respiratory failure [34,35].
Flow and pressure waveforms provide valuable information about respiratory system mechanics and patient–ventilator interaction. Used properly, these signals allow the clinician to garner diagnostic information, customize ventilator settings for the individual patient, and follow the impacts of treatments and time on the underlying respiratory disease. The amount of information obtained depends upon which mode is used to ventilate the patient, as well as whether the patient is actively or passively ventilated [5]. It is easiest to discern the mechanical properties of the respiratory system when VACV is used and flow is constant. Although it is possible to calculate respiratory system resistance and compliance from the flow waveform during PACV, this cannot be done easily or in real time [2]. Expiratory flow is mode-independent, depending on elastic recoil, expiratory resistance, and (unless there is flow limitation) patient effort.

Evaluating Respiratory System Mechanics

When using flow-targeted modes with constant flow, $P_{ao}$ during inspiration reflects the sum of three factors: (a) flow-related (resistive) pressure, $P_{resist}$; (b) elastic pressure due to lung volume and $C_{RS}$; and (c) total PEEP. With a few simple maneuvers, the total pressure can be partitioned into these three components, yielding insight into the underlying disease. In most mechanically ventilated patients, inspiratory $P_{ao}$ is elevated above normal values in line with the derangement in the respiratory system. Completely normal ventilator waveforms suggest a mechanically normal respiratory system, such as seen with pure neuromuscular failure, or may reveal that the cause of respiratory failure has resolved or been bypassed (such as when the endotracheal tube relieves major airway obstruction). The following discussion assumes a passive patient, but patient–ventilator interaction is described below. The peak inspiratory pressure (Ppk) represents the sum of $P_{resist}$ and the elastic recoil pressure due to tidal distention of the respiratory system plus total PEEP. With an end-inspiratory pause, pressure falls from $P_{pk}$ to a plateau ($P_{plat}$) by an amount equal to $P_{resist}$ (Fig. 166.10). At normal
inspiratory flows around 1 L per second, $P_{\text{resist}}$ is between 4 and 10 cm H$_2$O/L/s. Elevated $P_{\text{resist}}$ points to bronchospasm, airway edema, or other airway obstruction (tumor, secretion, mucus plugging, or partial endotracheal tube obstruction). It should be emphasized that a decelerating flow profile will lower $P_{\text{resist}}$, masking airflow obstruction.

**FIGURE 166.10** In passive patients ventilated with constant flow-targeted modes, the airway opening pressure is composed of resistive ($P_{\text{resist}}$) and elastic ($P_{\text{plat}}$) elements, with the latter also including PEEP (or autoPEEP). An end-inspiratory pause allows the determination of each of these components in the pressure wave curve. Note that pressure rises in two distinct phases: an initial step rise related mostly to the inspiratory resistance (thus very similar to $P_{\text{resist}}$), followed by a more gradual rise related to the respiratory system elastance.

With $P_{\text{resist}}$ known, the remaining pressure ($P_{\text{plat}}$) is the sum of the elastic pressure ($P_{\text{el}}$) related to tidal inflation of the respiratory system and total PEEP. When there is no autoPEEP, total PEEP is simply the set PEEP. Many patients have autoPEEP, however, so this should be sought by examining the flow waveform at end expiration (normally, expiratory flow should taper exponentially toward zero before the subsequent breath). AutoPEEP is present when there is persistent expiratory flow at end expiration (Fig. 166.11). It should also be suspected in the presence of elevated $P_{\text{plat}}$, electromechanical dissociation following intubation, and whenever there is PVD. The most common method to quantify autoPEEP.
is the end-expiratory port occlusion technique, but this is successful only when patients are passive. Alternatively, one can measure the change in esophageal pressure at the start of inspiration, but this requires an esophageal balloon. The magnitude of autoPEEP is often rather small, only 1 to 3 cm H$_2$O, and so typically has only a modest impact on measurements of respiratory mechanics. Nevertheless, it can rise to very high values (10 to 20 cm H$_2$O or even higher) among patients with severe airflow obstruction, as discussed in Chapter 30. In such instances, it is critically important to detect and monitor autoPEEP and to adjust the ventilator accordingly (see below).

**FIGURE 166.11** Pressure assist-control in a patient with airflow obstruction. Appreciate the persistent expiratory flow at end-expiration (arrow) revealing the presence of dynamic hyperinflation and autoPEEP. In passively ventilated patients, autoPEEP can be quantified by the end-expiratory port occlusion technique. At the time a breath is due, the ventilator closes the inspiratory and expiratory ports and withholds the expected breath, reflecting end-expiratory Palv, the autoPEEP pressure.

The final component of P$_{ao}$ is that required to expand the alveoli against the elastic recoil forces of the lung and chest wall, an amount that depends upon V$_T$ and the C$_{RS}$ (or its inverse, elastance, Ers). This pressure is found by subtracting P$_{resist}$ and total PEEP from Ppk. C$_{RS}$ can be calculated by dividing V$_T$ by this pressure; normal values are around 70 mL/cm H$_2$O. When V$_T$ is 400 mL, the compliance-related pressure should be about 6 cm H$_2$O (400 mL/70 mL/cm H$_2$O). Elevated pressures often signal high V$_T$, lung pathology (atelectasis, pulmonary edema, consolidation, etc.), or chest wall restriction (because of obesity, pleural
A subtle but important feature of the inspiratory $P_{ao}$ during constant-flow breaths is its normally linear rise, implying that $C_{RS}$ is not changing during the breath. The degree of linearity is described by the “stress index” which is equal to 1 when $P_{ao}$ rises in a straight line. If $P_{ao}$ rises with a concave upward shape (stress index > 1), $C_{RS}$ is falling during the breath, possibly revealing overdistention of lung. On the other hand, if $P_{ao}$ rises with a convex upward shape (stress index < 1), $C_{RS}$ is becoming greater during the breath—this may signal inspiratory recruitment (and implying expiratory derecruitment) (Fig. 166.12). This approach is one of many for setting the value of PEEP during lung-protective ventilation of ARDS.

Common disease patterns can be recognized by analyzing the pressure and flow waveforms (Fig. 166.13). The normal respiratory system
(assuming a passive patient and typical ventilator settings) shows a $P_{pk}$ of roughly 15 cm H$_2$O, $P_{plat}$ 10 cm H$_2$O, $P_{resist}$ 5 cm H$_2$O (calculated), and PEEP 5 cm H$_2$O. In addition, the early step-rise in pressure (in the first few milliseconds of the breath) is small (and similar to $P_{resist}$). Expiratory flow peaks at roughly 60% of the inspiratory flow and declines exponentially, falling to zero before the next breath. The patient with severe airflow obstruction, such as due to status asthmaticus, may have a $P_{pk}$ of 65 cm H$_2$O, $P_{plat}$ 20 cm H$_2$O, $P_{resist}$ 45 cm H$_2$O, and total PEEP 14 cm H$_2$O. The early step rise in $P_{ao}$ is abnormally large, related both to high $P_{resist}$ and to the presence of autoPEEP. An end-expiratory occlusion will show a value higher than the set PEEP. Expiratory flow is usually very abnormal with low peak expiratory flow rates, a biphasic shape, and low flow rates persisting until end-expiration. Finally, the patient with a restrictive pulmonary process may exhibit $P_{pk}$ of 40 cm H$_2$O, $P_{plat}$ 33 cm H$_2$O, $P_{resist}$ 7 cm H$_2$O, and PEEP 5 cm H$_2$O. The early step rise in $P_{ao}$ is normal. Expiratory flow is normal to increased and often ceases before the next breath begins.

**FIGURE 166.13** Volume assist-control ventilation. A: A patient with a restrictive pulmonary process: the pressure waveform shows an elevated $P_{pk}$ and $P_{plat}$, while the $P_{resist}$ appears small. The flow waveform shows high expiratory flow that ceases before the next breath begins. B: A patient with severe airflow obstruction: the pressure waveform shows an elevated $P_{pk}$ and $P_{resist}$ while the $P_{plat}$ appears normal. The flow waveform shows low flow rates throughout expiration. Note also that the early step rise in pressure is much higher in B, in accord with the much higher $P_{resist}$.

Although pressure-targeted modes are not recommended when seeking mechanical information about the respiratory system, some clues are
available nevertheless. When $P_{ao}$ is constant (PC breath), flow falls as alveolar pressure rises. Conditions characterized by a slow rise in $P_{alv}$ because of reduced lung recoil and airflow obstruction (such as emphysema) will show only a very slowly diminishing inspiratory flow rate (Fig. 166.14). In contrast, something like pulmonary fibrosis, in which $P_{alv}$ rises quickly during inspiration, is notable for a rapidly falling inspiratory flow rate. Finally, because expiration is mode independent, the same flow patterns seen during VACV will also be seen during pressure-targeted modes.

**FIGURE 166.14** Restriction versus obstruction during pressure-targeted ventilation. A: A patient with a restrictive pulmonary process: the inspiratory portion of the flow waveform falls quickly, because of the rapid rise in $P_{alv}$. The increased elastic recoil also drives rapid expiratory flow. B: A patient with severe airflow obstruction: the inspiratory portion of the flow waveform falls slowly, in line with the gradual rise in $P_{alv}$. The expiratory flow is slow and prolonged.
PATIENT VENTILATOR DYSSYNCHRONY

Definition

The degree of ventilatory support provided by MV extends from complete support to none. Both extremes of ventilatory support may be associated with structural injury of the respiratory muscles and subsequent muscle dysfunction and failure [36,37]. Thus, current strategies of MV aim to provide enough ventilatory support to achieve efficient gas exchange and match the patient’s demand. The ventilator and patient share the ventilatory work, facilitating respiratory muscle recovery with less sedation or muscle paralysis. Ideally, the patient and ventilator should synchronize during the three phases of breath delivery: triggering, flow delivery, and cycling off. The lack of optimal interaction is called PVD. This phenomenon results from inadequate or inappropriate ventilator settings (triggering, flow delivery, mode, and PEEP); excessive patient ventilatory drive; the presence of autoPEEP; and other poorly understand factors.

PVD is measured by three different methods: ventilator waveform analysis, esophageal pressure recordings, and electromyography of respiratory muscles, the last two being the most sensitive. Its prevalence can be as high as 80%, and is related to the type of dyssynchrony, ventilated population, method of detection used, the timing and duration of observation, the mode and settings of MV, and the presence of confounders like the degree of sedation [36,37].

Types

PVD can be classified by the phase of the breath in which it is seen but, for many patients, several types are present simultaneously. The origins of and responses to the different types of PVD are described below. Using NAVA greatly enhances synchrony during all breath phases, although any clinical benefits remain to be shown.

Triggering Phase

Ineffective Trigger. Also known as untriggered breath or trigger dyssynchrony. It is the most common form of PVD and refers to a
patient’s inspiratory effort (increase in transdiaphragmatic pressure or electrical activity of the diaphragm) after which there is no ventilator-delivered breath, or one that is delayed. Ventilator waveforms may show a subtle decrease in $P_{ao}$ not followed by a triggered breath; a change in the slope of exponential decay of the expiratory flow waveform; or transient cessation of expiratory flow during the expiratory phase (Fig. 166.15). Trigger dyssynchrony may result from dynamic hyperinflation, reduced respiratory drive, high levels of PSV, respiratory muscle weakness, or insensitive trigger settings in the ventilator. Ineffective trigger is quite common, especially when autoPEEP is present. Raising the level of ventilator PEEP helps to counter the inspiratory threshold load of autoPEEP, enhancing synchrony. For many patients, however, ineffective trigger is probably not clinically important. It can be reduced by treating autoPEEP or by reducing the $P_I$ during pressure-targeted breaths.

**FIGURE 166.15** Ineffective trigger. Ineffective trigger is evidenced in this patient by a subtle decrease in $P_{ao}$ not followed by a triggered breath (arrow) and a transient cessation of expiratory flow during the expiratory phase (arrowhead). Note also that expiratory flow ceases well before the third breath, marking a significant trigger delay (because the inspiratory threshold load of autoPEEP).

**Extra-Triggering**

- *Auto-triggering* occurs when the ventilator delivers an unscheduled
breath without a patient’s effort. It may occur when the triggering threshold is too low, in the presence of circuit leaks or vigorous cardiac oscillations, and related to condensation in the exhalation limb of the ventilator tubing (Fig. 166.16). This form of PVD is readily solved once the source of auto-triggering is recognized. Nevertheless, it can be subtle and has been reported to obscure the diagnosis of brain death.

- **Double-triggering or extra-triggering** consists of two consecutive inspirations with an interval of less than half of the mean inspiratory time ($T_I$) (Fig. 166.17). It usually accompanies high respiratory drive, low $V_T$ settings, or when neural $T_I$ exceeds machine $T_I$. Increasing the level of sedation appears largely ineffective in treating this type of PVD [38]. Raising minute ventilation or $V_T$ can suppress drive, although this may run counter to other goals of MV, especially for patients with ARDS or severe airflow obstruction. Often inserting a brief (e.g., 0.2 second) end-inspiratory pause is effective.

- **Reverse-triggering** (also called entrainment) [39], refers to the process whereby a machine breath elicits a spontaneous effort, seemingly mediated by vasovagal pathways and mechanical stretch receptors.

**FIGURE 166.16** Auto-triggering. Auto-triggering was recognized in this therapeutically paralyzed patient by the discrepancy between the patient’s respiratory rate (45/min) and the one set by the clinician (20). This patient had a circuit leak related to bronchopleural fistula: air lost through the chest tube mimicked the difference in flow between inspiratory and expiratory limbs of the ventilator that would be seen with inspiratory effort. (Note the discrepancy between inspiratory and expiratory tidal volumes). Auto-triggering resolved after switching flow- to
pressure-triggering.

**FIGURE 166.17** Double-triggering. Observe the presence of two consecutive inspirations (stars) with an inter-breath interval of less than half of the mean inspiratory time. Because little of each first breath is exhaled before the second breath is triggered, the effective tidal volume may be twice that set by the clinician.

p. 1507

p. 1508

**Flow Delivery Phase**

- *Flow dyssynchrony* occurs when the delivered inspiratory flow is insufficient to meet the patient’s ventilatory demand. This form of PVD is seen only during VA breaths. It can be detected by analyzing the pressure–time waveform, showing a concave appearance toward the Y axis (Fig. 166.18). If V₁ is set too low, raising it to the range of 60 L per minute or higher may be effective. Flow dyssynchrony resolves when switching from flow-targeted to pressure-targeted breaths, although this may allow higher than desired tidal volumes.

- *Excessive flow asynchrony* refers to the delivery of excessive flow, typically to patients with low inspiratory efforts. The rapid onset of flow can provoke discomfort and activate the expiratory muscles. Reducing V₁ (flow-targeted breaths) or P₁ (pressure-targeted breaths), or setting a rise-time of 0.1 to 0.2 seconds may ameliorate this form of PVD.
FIGURE 166.18 Volume-targeted mode in an active patient with flow dyssynchrony. Observe the concave appearance toward the Y-axis of the pressure waveform, most evident in the first and fourth breaths.

**Cycling Phase**

This type of asynchrony occurs when there is poor matching between machine $T_1$ and the patient (neural) $T_1$. It can manifest as:

- **Premature cycling** (machine $T_1 <$ neural $T_1$) manifested in very early expiration by a downward movement $P_{ao}$ (pressure–time curve during flow-targeted modes) and slowed expiratory flow (flow–time curve). This is often associated with double-triggering (Fig. 166.19).

- **Delayed cycling** (machine $T_1 >$ neural $T_1$) manifested by an elevation in $P_{ao}$ at end inspiration as the patient recruits expiratory muscles to oppose the ventilator pressure (pressure–time curve and flow-targeted modes) (Fig. 166.20). Following PS breaths, delayed cycling is common (especially in obstructed patients) but difficult to recognize. It may be signaled by the shape of the flow-time waveform, with flow suddenly cycling off rather than gradually declining.
FIGURE 166.19 Premature cycling (machine $T_I < T_{1e}$) in a patient ventilated on volume assist-control mode. Observe how inspiratory effort persists into machine $T_{E}$, slowing (and briefly stopping) expiratory flow (arrow). This is often associated with flow dyssynchrony (second breath) and double-triggering as evidenced in the last breath (star).

FIGURE 166.20 Patient ventilated on pressure support with delayed cycling (machine $T_I > T_{1e}$). Observe the sudden increase in the airway pressure at the end of inspiration (arrow), caused by expiratory effort from the patient. This can often be ameliorated by raising the flow threshold for breath termination, especially in patients with airflow obstruction.

Consequences

Observational studies suggest that PVD is associated with poor outcomes, including longer MV duration, shorter ventilator-free survival, longer
length of stay, higher rates of sleep pattern disruption, and lower likelihood of home discharge [18,40–42]. Although a causal relationship between PVD and poor outcomes has not been established, multiple mechanisms are postulated to explain these findings. PVD can compromise alveolar ventilation and gas exchange, worsen alveolar overdistention, and increase the work of breathing. Thus PVD could contribute to VILI, VIDD, intensive care unit acquired weakness (ICU-AW), or patient suffering. Furthermore, these consequences could worsen respiratory mechanics and potentiate further dyssynchrony, perpetuating this pathologic process. Finally, PVD is a common indication for the use of higher levels of sedation by ICU physicians, which coupled with the factors mentioned before may increase the length of MV, ICU stay, and perhaps mortality [6,36,43,44].
VENTILATOR-INDUCED LUNG INJURY

Definition

The term VILI refers to the functional and structural alterations that occur in the lung as a direct consequence of MV. VILI usually perpetuates and worsens the damage in injured lungs, but it can also initiate injury in previously healthy lungs, and may lead to multiorgan dysfunction [5,45].

VILI is classified into macroscopic and microscopic injury. Macroscopic injury consists of the presence of extra-alveolar air, and it is commonly referred as barotrauma. It includes pneumothorax, pneumomediastinum, pneumoperitoneum, subcutaneous emphysema, and cystic lung spaces. Peak airway pressure, level of PEEP, tidal volume, minute ventilation, patient–ventilation interaction, lung blood flow, and airway damage have been associated with the development of barotrauma, although this association and the pathogenetic mechanisms behind it remain controversial. Microscopic injury refers to the constellation of histopathologic changes in the lung triggered by MV, including the disruption of the alveolar–capillary barrier, impaired surfactant production, distal airway injury, release of inflammatory mediators, and formation of hyaline membranes and pulmonary edema [5,45].

Pathophysiology

VILI occurs mainly because of the overdistention of lung units by the use of excessive tidal volumes (volutrauma); and the use of low distending pressures that allow repetitive opening and closing of airways and alveoli (atelectrauma). In addition, the release of intracellular mediators from injured cells in response to those forces may promote further damage to the lungs directly or indirectly by activating epithelial, vascular and inflammatory cells that release more injurious molecules (biotrauma). Other factors like body temperature, respiratory acidosis, and pulmonary vasculature pressures may also be relevant to the development of VILI, although their pathologic role appears to be secondary [5,45–49].

Prevention

The transpulmonary pressure, the pressure difference between the alveoli ($P_{alv}$) and the pleural space ($P_{pl}$), is the effective alveolar distending pressure and correlates closely with the development of VILI. In conditions where the pleural pressure is nonsignificant (chest wall...
elastance is normal and the patient is passively ventilated), the transpulmonary pressure relates mainly to the alveolar pressure at the end of inspiration when the airflow is zero (plateau pressure). Thus, restricting plateau pressure is a commonly used strategy to limit the transpulmonary pressure and avoid alveoli overdistention. An alternative (or complementary) hypothesis is that the difference between $P_{\text{plat}}$ and PEEP (driving pressure) may be the key determinant of VILI [50].

Using low tidal volumes ($\approx 6$ mL/kg of PBW) and limiting $P_{\text{plat}}$ to less than 30 cm H$_2$O has been shown to reduce mortality by 22% in ventilated patients with ARDS, and is currently considered the standard of care in this patient population. A similar approach may also be beneficial in ventilated patients without ARDS [46,51,52]. Higher plateau pressures may be used in patients with poor chest wall compliance. Adequate levels of PEEP that minimize de-recruitment of alveoli and atelectasis may also be beneficial in preventing VILI. However, PEEP can also induce hyperinflation and alveolar overdistention in some patients. Thus, the appropriate level of PEEP has not been determined yet, and it may vary over time during the different stages of lung injury.

Measuring esophageal pressure allows for a more accurate calculation of the transpulmonary pressure to titrate PEEP and plateau pressure; this may improve outcomes in patients with ARDS [26]. Other suggested strategies for setting PEEP include the analysis of the PV curve and the shape of the pressure–time curve during constant flow inflation (“stress index”) [53]. Unfortunately, there are insufficient data to support the application of these strategies in routine clinical practice. This topic is addressed more fully in Chapter 30.

Permissive hypercapnia may be a necessary consequence of lung protective ventilation, although it should probably be avoided in patients with intracranial hypertension and perhaps in pregnancy.

Heart–Lung Interaction

The respiratory and cardiovascular systems are closely interconnected. MV affects the circulatory system directly through cyclic changes in the pleural pressure and indirectly by reducing the work of breathing and altering pulmonary vascular resistance. Two important consequences of MV relate to cardiac loading conditions and interpretation of intravascular pressures.

Cardiac Loading

For the passively ventilated patient, both PEEP and tidal inspiration raise Ppl, and these effects are amplified when chest wall compliance is
reduced. For the right ventricle (RV), the consequences include reduced preload and increased afterload. In severe ARDS, excessive $V_T$ or PEEP impairs cardiac output, usually by impeding RV ejection (as opposed to dropping preload) $[54–56]$. Acute cor pulmonale in this population is probably less common than in the past because lung-protective tidal volumes have less impact on the RV. Prone positioning also reduces RV afterload and can boost cardiac output $[57]$. For the LV, raising the pleural pressure increases preload, reduces afterload, and lessens mitral regurgitation. When LV function is poor, withdrawal of PEEP or MV may be attended by circulatory decompensation.

MV and PEEP also affect the circulation indirectly by improving gas exchange, lowering the work of breathing, and (when PEEP recruits substantially) lowering pulmonary vascular resistance. One of the mechanisms of weaning failure appears to be an inability of the circulatory system to handle the increased demands of spontaneous ventilation $[58]$.

Hemodynamic Interpretation

Because Ppl surrounds the heart, MV, PEEP, and spontaneous breathing alter the pressures measured in all cardiac chambers and the pulmonary circulation. These changes can be dramatic, especially when breathing effort is high or the chest wall compliance is greatly reduced. Because these effects are usually least at end expiration, all vascular pressures should be measured then. End expiration can be readily identified by ventilator waveform analysis. Patients with airflow obstruction often recruit expiratory muscles, artificially raising end-expiratory Ppl. There is no value in altering the ventilator or reducing PEEP simply to record a “better” value for right atrial or wedge pressure.

Ventilator-Induced Diaphragmatic Dysfunction

VIDD refers to the constellation of histologic, biochemical, and physiologic modifications that occur in the diaphragm as a direct consequence of MV. VIDD may result from diaphragm inactivity, and contributes to weaning failure. VIDD correlates with the duration of MV and seems to be aggravated by sepsis and severity of illness. VIDD appears to be mediated by mitochondrial dysfunction with increase in oxidative stress, and activation of several catalytic pathways (ubiquitin–proteasome, caspases, calpains), which result in diaphragmatic muscle fiber injury and remodeling, decreased contractility, and atrophy.
Lysosome-mediated autophagy is also upregulated in the diaphragm of ventilated patients, but this appears to be a beneficial adaptive response to remove the damaged mitochondria and alleviate VIDD [59–69].

Maintaining spontaneous respiratory efforts during MV is associated with decreased VIDD in animal models and in some observational human studies. Furthermore, the use of targeted therapies to block oxidative and catabolic pathways has also been shown to improve VIDD in animal experiments. However, the lack of adequate data from human studies precludes the use of these strategies in current clinical practice [70–74].

**Ventilator Settings According to Disease Type**

Most ventilated patients can be classified into four phenotypes based on the mechanical properties of the respiratory system: (1) Normal gas exchange and respiratory mechanics; (2) ARDS; (3) Significant airflow obstruction; (4) Restriction of the chest wall. The principles underlying ventilator management differ between these groups so that initial settings should be individualized. Subsequently, the clinician should adjust these initial settings according to the patient–ventilator interaction and the respiratory system mechanical properties as revealed by pressure and flow waveform analysis. Thereafter, settings should be further altered as the underlying disease evolves. In addition, a “ventilator bundle,” consisting of head-of-bed elevation; daily sedative interruption; readiness testing for spontaneous breathing; and other preventive steps should generally be provided to all ventilated patients.

**Normal Gas Exchange and Mechanics**

Patients with normal lungs may be ventilated in the perioperative setting; for drug overdose; in the setting of brain injury; or for other neuromuscular crises. These are the easiest patients to ventilate and, when they recover from the procedure or process, most are easily liberated from MV. Principles include achieving relatively normal arterial blood gas tensions and reducing the risk of complications, such as by using the ventilator bundle. Common ventilator settings include any of several modes (VACV, PACV, or, if drive and strength are adequate, PSV); PEEP 5 cm H₂O; FiO₂ 0.3 to 0.4; tidal volume of 6 to 10 mL/kg PBW; and inspiratory flow rate 50 to 60 L per minute. Respiratory rate is often set at a value that encourages the patient to initiate breaths if this is clinically appropriate, because this may reduce the risk of VIDD. Periodic assessment of ventilator waveforms facilitates appropriate settings for rate. There is controversy about how much VT should be limited. An association has been described between lower VT (e.g., 6 mL/kg PBW)
and reduced risk of developing ARDS and improved survival [75].

**Acute Respiratory Distress Syndrome**

Guiding principles involve providing adequate oxygenation and reducing the risk of VILI by limiting $V_T$ or driving pressure. A large prospective trial showed a significant reduction in mortality simply by ventilating with 6, rather than 12 mL/kg PBW [46]. Whether to use higher or lower PEEP is controversial: any benefit may relate to whether an individual patient has a higher or lower potential for PEEP-induced lung recruitment. A retrospective analysis suggested that driving pressure ($P_{\text{plat}} - \text{PEEP}$) was more related to survival than the specific values of $V_T$ and PEEP [50]. Patients ventilated with driving pressure $\leq 14$ cm H$_2$O had better outcomes.

A consequence of limiting $V_T$ or driving pressure is that some patients will experience hypercapnia. This appears to be well tolerated in adequately sedated patients, although it may be less safe in pregnancy, with intracranial hypertension, and during active myocardial ischemia. For most patients with ARDS, however, the benefits of lower $V_T$ likely outweigh any potential harms from respiratory acidosis.

Typical ventilator settings in ARDS include: $V_T$ 6 mL/kg PBW (best achieved using VACV or PRVC modes); rate 26 to 35 per minute; inspiratory flow rate 50 to 60 L per minute; and increased FiO$_2$. The preferred level of PEEP remains controversial [76].

**Airflow Obstruction**

The most important guideline for ventilating patients with severe airflow obstruction is to avoid dangerous degrees of hyperinflation. This is best achieved by limiting minute ventilation to less than 10 L per minute. This will be attended by hypercapnia far more often than in patients with ARDS, but appears safe. The degree of hyperinflation can be monitored by measuring autoPEEP or $P_{\text{plat}}$. PEEP should be used to ease the work of triggering; although 5 cm H$_2$O is often sufficient, some patients will benefit from values of 10 cm H$_2$O or higher. Some clinicians prefer pressure-targeted modes because these intrinsically limit the degree of hyperinflation (because hyperinflation tends to reduce $V_T$), but flow-targeted modes allow control over minute ventilation. Synchrony can be enhanced using NAVA, but no clinical benefit has yet been shown.
Chest Wall Restriction

Chest wall restriction is seen among patients with severe kyphoscoliosis, abdominal compartment syndrome, large ascites, circumferential burns, and massive obesity. The crucial challenge in these patients is that, during passive ventilation, the inspiratory rise in Ppl is proportional to chest wall elastance and VT. Large tidal volumes risk hemodynamic compromise, so the principles of MV include limited VT and minimum PEEP. In these patients it may be preferable to use higher fractions of oxygen than to raise PEEP. Although high values for Pplat may not signal lung overdistention, they are best avoided nevertheless to prevent cardiovascular effects.
EXTRACORPOREAL LIFE SUPPORT

Introduction

ECLS utilizes an extracorporeal circuit, membrane lung, and (usually) blood pump to support patients with severe respiratory or cardiac failure as a bridge to recovery or to definitive therapy (like organ transplantation). Although a highly complex therapy, recent refinements of circuit design and safety allow ECLS to be carried out in an ICU; sustained for days to months; and supervised by an intensivist and ICU nurse (assisted by an ECLS specialist—nurse or respiratory therapist—in many centers). Simpler, modular circuits facilitate interhospital transfer; transport for diagnostic testing or to the operating room; and mobilization for physical therapy and rehabilitation.

Currently, the most common indication for ECLS in adults is severe ARDS, where it has three major roles: (1) ECLS can be life-saving for catastrophic failure of gas exchange. This was the original concept, but is applicable to only a small proportion of ARDS patients. (2) For patients with ARDS, ECLS may limit VILI by relieving the native lung of the burden of gas exchange; (3) ECLS may facilitate early extubation and mobilization of patients, enhancing recovery and rehabilitation or improving the chances of surviving to transplantation [77]. ECLS plays a lesser role for patients with hypercapnic respiratory failure; postoperative circulatory failure; refractory cardiac arrest; and as a bridge to lung transplantation.

Key Circuit Components

Membrane Lung

The central feature of an ECLS circuit is the membrane lung, sometimes referred to as an oxygenator. This device has a semipermeable membrane separating blood and its cellular elements from the gas phase, while allowing diffusion of oxygen and carbon dioxide. Newer hollow-fiber, polymethylpentene membranes are highly efficient gas exchangers, have a large surface area for diffusion, and present low resistance to blood flow. These characteristics allow rapid blood flow rates using simple, centrifugal pumps, while being compact and reliable. The entire metabolic demand for oxygen can be met easily with a single device the size of a fist. Gas is supplied from wall oxygen or a gas cylinder, through a blender that regulates the fraction of oxygen, directed into the hollow fibers of the membrane, then out an exit port.
Vascular Cannulae

Blood exits and rejoins the circulation through vascular cannulae placed into large, central vessels. The size and location depend upon the mode of ECLS used, as described below. It is these cannulae that largely determine blood flow rates through the entire ECLS circuit, so it is critically important to use a size sufficient to achieve the aims of ECLS. Cannulae can be inserted by three different methods: (1) extrathoracic percutaneous approach by the Seldinger technique, (2) open surgical technique, usually used for cannulation of central arterial vessels, and (3) semiopen cutdown approach, which is a variation of the percutaneous technique, but with direct visualization of the vessel cannulation [30,59]. Dual-lumen cannulae allow both withdrawal and return of blood through a single access site, but fluoroscopic or echocardiographic guidance is recommended for insertion to reduce the risk of major vessel or right ventricular injury.

Blood Pump

Centrifugal pumps have largely replaced roller pumps, a major safety advantage afforded by the low blood resistance of modern membrane lungs. These pumps also are less traumatic to blood elements, producing less hemolysis. Some can be operated by hand in the event of power failure. By adjusting the speed of the pump, the operator controls blood flow rate.

Miscellaneous Components

ECLS circuits incorporate varying degrees of monitoring, often displaying pump speed; blood flow rates; hydrostatic pressures in the blood stream before and after the membrane; and temperature. Sensors may show blood gas tensions and other biochemical data and are used to detect bubbles within the circuit or signal other potential crises. Access points are provided for giving fluids and blood products; sampling blood for laboratory testing; removing air inadvertently introduced into the circuit; infusing heparin; or incorporating renal replacement therapies. A blood warmer is used to prevent hypothermia.

Extracorporeal Life Support Modes and Physiology

There are three conventional modes of ECLS, distinguished by the type of vascular access (venous or arterial) and the organ support provided (pulmonary and/or cardiovascular).

Venovenous (V-V) ECLS: This is the most common modality used for
patients with severe respiratory failure. Blood is withdrawn from a large central vein, directed by the pump into the extracorporeal circuit, and returned to the venous circulation. Vascular access can be provided by a two-site approach in which a drainage cannula (23 to 29 Fr) is placed in a central vein, usually the femoral vein, extending to the vena cava. The return cannula (21 to 23 Fr) resides in another central vein (internal jugular or contralateral femoral vein) extending into the right atrium. Even though the cannulae are in separate locations, turbulence in the venous circulation may allow some oxygenated blood to be withdrawn again and sent to the extracorporeal circuit. This process, termed “recirculation” reduces the efficiency of gas exchange.

The single-site approach utilizes a dual-lumen cannula usually placed through the internal jugular vein and extended across the right atrium to the inferior vena cava. Blood is withdrawn through ports situated in both inferior and superior vena caval portions of the cannula, sent to the extracorporeal circuit, and returned through the second lumen into the right atrium where a jet is directed toward the tricuspid valve. When the dual-lumen cannula is well positioned, oxygenated blood passes through the tricuspid valve to the RV, reducing the degree of recirculation. Some degree of recirculation is seen nevertheless, especially if the cannula is positioned poorly or when blood flow rates are high. Other advantages of single-site cannulation are simplicity, fewer sites for vascular injury, and ease of getting the patient out of bed to sit, stand, or walk. On the other hand, these are very large catheters (often 31 Fr).

V-V ECLS is ideal for treating patients with ARDS as long as the native circulation is intact. Because this mode drains and returns equal volumes of blood, it does not directly support the circulation, although delivering highly oxygenated blood to the pulmonary artery may unload the RV when there is hypoxic pulmonary vasoconstriction. For ARDS patients with acute cor pulmonale or other causes of shock, venoarterial (V-A) ECLS is preferred. V-V ECLS readily bears the full oxygenation demand, as long as a sufficient fraction of the cardiac output (roughly 70%) can be captured and directed to the extracorporeal circuit. Thus good cannula positioning and adequate diameter are crucially important for treating ARDS. Arterial saturations are often in the mid-80s to low 90s, which is adequate for maintaining oxygen transport.

V-V ECLS can also emphasize carbon dioxide (CO₂) removal (extracorporeal CO₂ removal, ECCO₂R). In fact, the membrane lung is much more efficient at eliminating CO₂ than boosting oxygenation, so that less blood flow is required. For example, a circuit flow of roughly 1 L per minute is sufficient to eliminate the entire volume of CO₂ produced metabolically, meaning that smaller-bore catheters can be employed. V-V ECLS may be suitable for treating exacerbations of COPD or status...
asthmaticus if its complications (mostly bleeding) are outweighed by those of invasive ventilation. ECCO$_2$R has also been used in ARDS in order to reduce V$_T$ to 3 to 4 mL/kg PBW to further reduce the risk of VILI, so called “ultra-protective” ventilation.

Venoarterial (V-A) ECLS

This mode is used to provide circulatory support, in addition to oxygenation. Blood is withdrawn from the venous system, passed through the extracorporeal circuit for gas exchange, and returned to the patient’s arterial system using the pump to produce sufficient pressure. The drainage cannula (23 to 29 Fr) is usually inserted into the femoral vein extending to the inferior vena cava. The cannula for blood return (17 to 19 Fr) is inserted into the femoral artery (ipsilateral or contralateral) extending to the distal abdominal aorta. The returning blood will generate retrograde blood flow in the aorta which can increase the cardiac afterload with negative consequences for the failing heart. To prevent this phenomenon, the blood flow is usually maintained at somewhat lower rates than during V-V ECLS [78].

Unlike during V-V ECLS, blood captured by the withdrawal cannula bypasses the heart and the lungs completely, decreasing cardiac filling pressures and pulmonary blood flow, while maintaining adequate systemic perfusion. There are two peculiarities, however: (a) the systemic blood pressure lacks normal pulsatility unless there is residual native pump function; (b) oxygen saturation varies along the aorta (and its branches) as desaturated blood ejected from the dysfunctional heart mixes with highly oxygenated blood returned to the distal aorta. Thus the coronary vessels, right arm, and head may be supplied with blood much less oxygenated than that seen by the left arm or lower extremities. V-A ECLS is usually used in one of three clinical scenarios: (1) Failure to wean from cardiopulmonary bypass; (2) Biventricular or right heart failure combined with lung failure; or (3) Extracorporeal cardiopulmonary resuscitation (eCPR) [79].

Arteriovenous (A-V) Pumpless ECLS: This mode uses the same principle as venovenous ECCO$_2$R removal but with a pumpless circuit, using the patient’s own blood pressure as a driving force for circuit flow. This is made possible by the low blood flow resistance of polymethylpentene hollow-fiber membranes. The drainage cannula is inserted into the femoral artery extending to the distal abdominal aorta. The cannula for blood return is placed in the contralateral femoral vein.
Even with relatively small cannulae, blood flow is sufficient for quite substantial CO$_2$ removal (although not for oxygenation), averaging about 150 mL per minute, about 75% of metabolic production [77,78].

Supportive Therapies During Extracorporeal Life Support

Mechanical Ventilation

Because ECLS supports gas exchange, the role of the mechanical ventilator is uncertain. Most often, ventilator settings similar to those thought to confer lung protection are chosen: low tidal volume (≤6 mL/kg PBW) or driving pressure (<14 cm H$_2$O); adequate PEEP (10 to 15 cm H$_2$O); low FiO$_2$ (0.3 to 0.4); and very low respiratory rate (6 to 10 breaths per minute) [78,80,81]. Low tidal volume ventilation with low end-inspiratory plateau pressures during ECLS was associated with lower levels of inflammatory biomarkers [82]. Some large observational studies in ECLS patients suggest that lower PEEP and high plateau pressures are associated with higher mortality, despite the use of low tidal volume [80,83].

Anticoagulation

Systemic anticoagulation is used during ECLS to avoid thrombus formation in the circuit, but brief periods off anticoagulation are often tolerated well. Heparin is traditionally employed, but argatroban has been used in patients with heparin-induced thrombocytopenia. Patients are at risk of both thrombosis and hemorrhage during ECLS, making the ideal anticoagulant drug, anticoagulation target, and means of monitoring controversial. Platelet number and function; coagulation proteins; endogenous anticoagulants such as antithrombin-III; and the fibrinolytic system are often abnormal relating to critical illness or ECLS itself. Some have proposed that monitoring with thromboelastography might provide additional insights into how best to reduce the risks of bleeding and clotting.

Mobilization

Critical illness and MV have been associated with ICU-AW and VIDD. Both processes involve complex inflammatory and catabolic muscle pathways that start early in the course of the critical illness, worsen progressively, and persist usually for years [77]. Early mobilization of
ventilated patients inhibits catabolic pathways and is associated with improved ventilator-free days; reduced delirium; less risk of ICU-AW and VIDD; decreased length of hospitalization and ICU stay; and lower long-term disability [84]. Despite these benefits, historically most ECLS patients were managed with deep sedation or paralysis to avoid accidental decannulation, bleeding, or limb ischemia [77].

Safer ECLS circuits, increasing use of single-site, dual-lumen cannulae for VV-ECLS, and recognition that deep sedation is often not necessary has decreased the burden of mobilizing patients. Now it is common for patients to sit, stand, and walk while on ECLS [77]. This is especially true of the bridge-to-transplant population who often have single organ failure [77]. Nevertheless, this should only be attempted with a team experienced in mobilizing complex, critically ill patients.

Clinical Evidence and Indications

The first clinical trials comparing ECLS to ventilatory management in adults with ARDS failed to show benefit [85,86]. In retrospect, these trials were doomed by technologic limitations; use of the V-A mode with its attendant higher bleeding risk; and late initiation of ECLS (>9 days) after the ravages of VILI were probably irreversible [79]. The CESAR trial, published in 2009, is the largest randomized, multicenter, controlled trial performed using modern ECLS technology. In this study 180 adults age 18 to 65 with severe respiratory failure were randomized to conventional management at one of several designated hospitals in the UK, versus referral to a specialized center (Glenfield Hospital in Leicester, England) where they received a standardized management protocol (lung-protective ventilation, diuresis, prone positioning, and consideration for ECLS). This study produced new enthusiasm for ECLS when its positive findings were published: patients referred for ECLS had a lower rate of death or disability at 6 months compared to the conventional group (37% vs. 53%; RR: 0.69; 95 CI 0.05–0.97; p = 0.03). Despite the positive findings, this trial has important limitations. Of the subjects referred to Leicester, only 76% received ECLS. It is not possible to know whether outcomes were better because of ECLS or because of generally improved care at the referral center (which was more likely to provide lung-protective ventilation and other beneficial treatments) [87].

Subsequently, several observational studies of ECLS for patients with severe respiratory failure, dominated by populations with influenza A (H1N1), gave mixed results [88–90]. Thus, there is no consensus about
the role for ECLS and little evidence base for guiding who might benefit from it. A better prediction tool for survival may improve the allocation of ECLS resources. The RESP score (http://www.respscore.com/) has been recently developed using the Extracorporeal Life Support Organization (ELSO) international registry, which includes 2,355 adult patients with severe acute respiratory failure treated by ECLS from 2000 to 2012. This score has been validated in large cohorts and is intended to help clinicians identify patients most likely to survive and benefit from ECLS. The RESP score uses 12 pre-ECLS clinical variables to classify patients into five different classes (I to V) of predicted hospital survival: 92% in class I, 76% in class II, 57% in class II, 33% in class IV, and 18% in class V. A limitation of this score is the lack of inclusion of prone positioning as one of the variables in the calculation of hospital survival probability [91].

Current indications for ECLS promulgated by the ELSO are listed in Table 166.3 [92]. Contraindications include significant comorbidities; advanced age; terminal illness; established VILI; or any condition precluding systemic anticoagulation. Many centers use the exclusion criteria from the CESAR trial: MV with FiO₂ greater than 0.80 and plateau airway pressure above 30 cm H₂O for more than 7 days [77,78].

**TABLE 166.3 Indications and contraindications of ECLS in adults with respiratory failure**

**Indications**

1. Severe hypoxemia when the risk of mortality is 80% or greater (PaO₂/FiO₂ < 150 on FiO₂ > 0.9 and or Murray score 2–3)
2. CO₂ retention on mechanical ventilation despite high Pplat (>30 cm H₂O)
3. Severe air leak syndromes
4. Need for intubation in a patient on lung transplant list
5. Immediate cardiac or respiratory collapse (massive pulmonary embolism, airway obstruction, etc.)

**Relative contraindications**

1. Mechanical ventilation at high settings (FiO₂> 0.9; Pplat > 30 cm H₂O) for 7 days or more
2. Major pharmacologic immunosuppression (absolute neutrophil count < 400/mm³)
3. CNS hemorrhage, recent or expanding
4. Nonrecoverable comorbidities, like terminal malignancy or major CNS damage
5. Age: No specific age is contraindicated, but consider increasing risk with
increasing age

There are no absolute contraindications to ECLS, and the risk-to-benefit ratio should be evaluated individually for each patient.

CNS, central nervous system; ECLS, extracorporeal life support

An ongoing international, multicenter, randomized, and open trial (EOLIA; NCT01470703) will compare the 60-day all-cause mortality between patients treated with lung-protective MV in combination with early ECLS (within 3 to 6 hours after optimal medical management) versus those treated with lung protective ventilation alone. This trial is planning to enroll 331 participants with severe respiratory failure from October 2011 through February 2016.

The use of ECO₂R is based on limited clinical trial data. In one series of patients with ARDS and worsening hypercapnia, ECO₂R corrected CO₂ levels rapidly and modestly raised PO₂ [82,93,94]. In a prospective randomized trial, ECO₂R with ultraprotective ventilation (3 ml/kg) was compared to conventional low-tidal volume ventilation. Although there were no differences of ventilator-free days at 28 and 60 days, a post hoc analysis of patients with PaO₂/FiO₂ ≤ 150 showed a significant improvement in the number of ventilator-free days at 60 days when treated with the ultra-protective strategy [95]. For patients with hypercapnic respiratory failure due to obstructive lung diseases, small case series show benefits such as early extubation and ambulation [96–98]. The lack of adequate clinical trials in this field precludes the generation of clear guidelines for the use of ECO₂R.

The use of ECLS as a bridge to lung transplantation has been studied in small series with mixed results, and remains controversial [77,78,99,100]. MV preceding lung transplantation is associated with worse survival and higher rates of retransplantation, leading to interest in awake ECLS as a means to avoid MV [101–103]. A single-center, retrospective study using a historical control group suggested higher survival 6 months after lung transplantation among patients treated with awake ECLS versus those receiving MV (80% vs. 50%, p = 0.02) [102]. ECLS has been also studied in retrospective series as a rescue therapy for patients developing severe primary graft dysfunction following lung transplantation. These showed improved immediate survival, but mixed results in allograft function and long-term survival [78,104–106]. Early institution of ECLS for patients with lung transplant developing severe primary graft dysfunction may be associated with better outcomes [107].

The evidence supporting V-A ECLS for cardiac support is sparse [77,78]. Limited data suggest a role in refractory cardiac arrest, especially if this can be instituted rapidly [108–110].
Indications for Extracorporeal Life Support for Patients with Respiratory Failure

In the past, ECLS was considered just a rescue therapy for critically ill patients that failed to improve with conventional MV, prone positioning, and inhaled vasodilators. The advances of ECLS technology have decreased the complexity of the circuit and improved the oxygenation efficiency, making the respiratory support provided by MV less necessary. This may allow earlier extubation and liberation from MV, with a potential reduction of sedation use and delirium incidence, as well as an increase in early mobilization. Thus, ECLS may soon be seen as an early intervention that intensivist physicians can incorporate into their armamentarium to treat patients with respiratory failure, and avoid or potentiate adverse events like VILI, delirium, ICU-AW, VIDD, long-term disability, and perhaps even mortality [4]. ECLS should be performed at centers with physicians experienced in its use, and with established protocols. Centers with a higher volume of ECLS procedures have better outcomes. The ELSO recommends that ECLS centers should perform at least six cases per year, and ideally 15 to 20 per year. Earlier initiation has also been associated with better outcomes in some observational studies [77,78].

Adverse Effects and Complications

The most common complications associated with the use of ECLS are infections, bleeding, thrombosis, and distal limb ischemia. The rates of complications are higher with V-A ECLS than with V-V ECLS.

Chapter 167
INTRODUCTION

Noninvasive ventilation (NIV) is the provision of mechanical ventilation without the need for an invasive artificial airway. NIV can be subdivided into a number of modalities with different mechanisms of action, including negative pressure ventilation that assists lung expansion by applying an intermittent negative pressure over the chest and abdomen, positive pressure ventilation that applies continuous or intermittent positive pressure to the upper airway, and abdominal displacement ventilators like pneumobelts and rocking beds that assist ventilation at least partly via the force of gravity on the abdominal contents [1–3]. Over the past two decades, noninvasive positive pressure ventilation (NPPV) [4] via the nose, mouth, or combination has become the predominant mode of NIV in both the outpatient and hospital settings, and henceforth will be referred to as “NIV” or “NPPV”. In this chapter, we focus on acute applications, comparing and contrasting noninvasive and invasive approaches and describing epidemiologic trends of NIV. Next, we describe the equipment used for NIV and discuss indications and selection of patients for NIV in acute care settings. We then make recommendations regarding the practical and safe application of NIV, including selecting the proper location, appropriate monitoring, and avoiding complications. Finally, we consider the possible impact of newer approaches including high-flow nasal therapy (HFNT) and extracorporeal CO₂ removal (ECCO₂R) techniques.
TERMINOLOGY

As used in this chapter, NIV is a generic term for a number of different noninvasive approaches to assisting ventilation, whereas NPPV refers specifically to the form that facilitates ventilation by applying a positive pressure to the upper airway. This can be continuous positive airway pressure (CPAP) that can be used to successfully treat certain forms of respiratory failure or intermittent, combining a positive end-expiratory pressure (PEEP) with pressure support (PS) ventilation, the latter used to actively assist inspiration. Some ventilators are derived from portable positive pressure devices to treat sleep apnea and are commonly referred to as bilevel positive airway pressure (BPAP) devices. With these, the term expiratory positive airway pressure (EPAP) is used rather than PEEP and inspiratory positive airway pressure (IPAP) refers to the total inspiratory pressure. Thus, the difference between IPAP and EPAP equals the level of pressure support.
WHY NONINVASIVE MECHANICAL VENTILATION?

NIV has seen increasing popularity in acute care settings throughout Europe and the United States over the past two decades [5,6]. This trend is related to a number of advantages of NIV over invasive mechanical ventilation (IMV), but only for selected patients. By averting invasion of the upper airway, NIV avoids a number of well-known complications of intubation, including aspiration of gastric contents, dental trauma, trauma to the hypopharynx, larynx, and trachea including tracheal rupture [7], hypoglossal nerve paralysis, stimulation of the autonomic nervous system leading to arrhythmias, and hypotension [8]. Ongoing use of invasive ventilation increases the risk of ventilator-associated pneumonia (VAP) related to disruption of airway protective mechanisms, pooling of secretions above the tube cuff that leak into the lower airways, and formation of a bacterial biofilm within the tube that is distributed peripherally during suctioning. In addition, irritation from the tube stimulates mucus secretion and interferes with normal ciliary function. The need for repeated suctioning further traumatizes the airway and promotes bleeding and mucus secretion. Following extubation, immediate complications can include upper airway obstruction due to glottic swelling, negative pressure pulmonary edema, tracheal hemorrhage, and laryngospasm [9,10]. Complications of prolonged invasive ventilation (in association with tracheostomy) can include a spectrum of repeated airway and parenchymal infections, vocal cord dysfunction, tracheal stenosis, or malacia [4,11–13].

In addition, NIV is usually better tolerated than invasive ventilation, requiring less or no sedation. It usually permits short breaks that help to enhance tolerance. The avoidance of intubation-associated complications and sedation promotes more rapid weaning compared to invasive ventilation, shortening intensive care unit (ICU) stays and potentially reducing resource utilization and costs. On the other hand, NIV should not be considered as a replacement for IMV. When used appropriately, NIV serves as a way to avoid intubation and its attendant complications, but it must be used selectively, avoiding patients who have contraindications (see “Selection Guidelines for NIV in Acute Respiratory Failure” section). Appropriate candidates must be able to protect their airways and cooperate. Sometimes, NPPV is initiated for inappropriate or marginal candidates who fail to respond favorably. In this situation, it is important to intubate promptly, avoiding delays that can lead to cardiopulmonary arrest, necessitating emergency intubation and
increased morbidity and mortality [14].
UTILIZATION AND EPIDEMIOLOGY

Rates of NIV utilization in acute care settings have increased in Europe and North America [15,16]. An observational study of NIV utilization for chronic obstructive pulmonary disease (COPD) and cardiogenic pulmonary edema (CPE) patients with acute respiratory failure (ARF) at a single 26-bed French ICU revealed an increase from 20% of ventilator starts in 1994 to nearly 90% in 2001 [15]. In association with this increase, the occurrence of health care–acquired pneumonias and ICU mortality fell from 20% and 21% to 8% and 7%, respectively. The authors speculated that increasing experience and skill with NPPV in their units contributed to the improved outcomes. In a US study examining utilization and outcomes of NPPV in 8 Massachusetts hospitals during 2004 to 2007, overall use of NIV as a percent of ventilator starts was 38.5% with a success rate of 73.9%. For ARF due to COPD exacerbation, use was 82.2% with a success rate of 75.7%, and for pneumonia, use and success rates were 41.4% and 47.2%, respectively [16]. This represents a substantial increase over prior surveys. Chandra et al. [6], using the US National Inpatient Sample of patient admissions, identified over 7.5 million COPD admissions during the years 1998 to 2008 and noted a 462% increase of the use of NIV and a concomitant 42% decline for the use of IMV. These trends are apparent throughout the world. Esteban et al. have conducted worldwide prospective 1 month surveys from 40 countries that compared the trends of mechanical ventilation use and outcomes between 1998, 2004 and 2010, enrolling more than 18,000 patients. During this time period, the surveys showed a nearly threefold increase in percent NIV ventilator starts (5% to 14%) and a reduction of overall mortality of ventilated patients (31% to 28%) [17].

In the past, several studies reported variable use of NIV depending on the hospital. A 2003 national audit of COPD exacerbations in the United Kingdom revealed that NIV was unavailable 39% of ICUs and 36% of “high-dependency units” [18]. Similar results were seen by a North American survey of NIV use showing an estimated usage rate of 20% overall, but 30% of hospitals had estimated rates <15%. Reasons for low utilization were mostly attributed to lack of physician knowledge of NIV, inadequate equipment, and lack of staff training. Most disturbingly, estimated use of NIV for COPD exacerbations and CPE was only 29% and 39% of ventilator starts, respectively [19]. Even more disturbing, a
Korean survey reported that NIV was used in just 2 of 24 university hospitals and comprised only 4% of ventilator starts. A majority of the physician staff (62%) and 42% of the nurses expressed a desire for additional educational programs on NIV [20].

Analyses of large databases have been helpful for highlighting these trends of increasing use of NIV. Using the Premier database consisting of 420 US hospitals, Lindenauer et al. [21] found that among 25,628 COPD patients, 70% were initially treated with NIV and 30% with IMV. Fifteen percent of patients who were initially treated with NIV later required IMV, indicative of NIV failure. Stefan et al. [22] using the same database for the years 2001 to 2011 observed a 15.1% annual increase in use of NIV for COPD patients and a 3.2% annual decrease of the use of IMV. NIV was used for a greater proportion of older patients (>85 years) than for those <65 years of age. Similar trends toward increased NIV use have been reported for patients with non-COPD diagnoses [22], raising the possibility of overzealous use of NIV for some of these patients. The observation by several investigators that mortality of NIV failures exceeds that of patients intubated in the first place also raises the possibility of overzealous use [6,22].
INDICATIONS FOR ACUTE APPLICATIONS OF NPPV

Indications for NIV depend on the etiology of ARF and specific settings in which ARF occurs (i.e., do-not-intubate [DNI] patients). As much as possible, our analysis is based on available evidence. We recommend application of NIV for those diagnoses that are those supported by multiple randomized trials. We consider NIV as an “option” when the application is supported by a single randomized trial, multiple historically controlled or cohort series, or evidence is not consistent. Successful application of NIV has been reported for all of these indications when applied for appropriately selected and monitored patients (Table 167.1).

TABLE 167.1 Indications for Noninvasive Positive Pressure Ventilation as Determined by Strength of Evidence

Recommended (supported by strong evidencea)
- COPD exacerbations
- COPD—failure to wean from invasive mechanical ventilation
- Acute cardiogenic pulmonary edema

Option (supported by weaker evidenceb)
- Other obstructive airway diseases with acute respiratory failure
- Asthma exacerbation
- Cystic fibrosis
- Immunosuppressed patients with acute respiratory failure
- Hypoxemic respiratory failurec
- ALI/ARDS (carefully selected patients)
- Community-acquired pneumonia
Trauma
Extubation failure
Mainly patients with COPD or CHF
Postoperative respiratory failure
Prophylactic use of CPAP or “bilevel” after high-risk surgeries
Treatment of acute respiratory failure—mainly COPD or CHF
Do-not-intubate patients
To treat acute respiratory failure (COPD or CHF)
To palliate for relief of dyspnea or extend survival to settle affairs
Obesity hypoventilation
Neuromuscular disease
Partial upper airway obstruction (postextubation)
Not recommended
ALI/ARDS with multiorgan system dysfunction or hypotensive shock
End-stage pulmonary fibrosis with exacerbation
Total or near total upper airway obstruction

\[\text{a}\] Strong evidence refers to multiple randomized controlled trials and meta-analyses.

\[\text{b}\] Weaker evidence refers to mainly case series, case-matched series, single randomized trials, or some conflicting data.

\[\text{c}\] Must be monitored very carefully—not a routine indication.

ALI/ARDS, acute lung injury/acute respiratory distress syndrome; COPD, chronic obstructive pulmonary disease; CHF, congestive heart failure; CPAP, continuous positive airway pressure.

Recommended Indications
Chronic Obstructive Pulmonary Disease

**COPD Exacerbations.** The best established acute indication for NIV is to treat ARF due to COPD exacerbations. This is supported by a strong physiologic rationale. Studies demonstrate that the combination of extrinsic PEEP and PS reduce diaphragmatic work of breathing more than either modality alone, because the expiratory pressure counterbalances intrinsic PEEP and the higher inspiratory pressure (pressure support) actively assists the inspiratory muscles [23]. In the setting of COPD exacerbations, NIV thereby serves as a “crutch” to assist ventilation while medical therapies are given time to work.

Multiple randomized controlled trials (RCTs) and meta-analyses of COPD patients with ARF have established that NIV more rapidly reduces respiratory rate, improves dyspnea and gas exchange, reduces intubations from a rate of 50% to 20%, and lowers mortality compared to standard therapy [4,21,24–27]. This evidence has recently been bolstered by Lindemaur’s study using the PREMIER database [21] which showed in a propensity adjusted analysis that NIV was associated with lower risks of mortality and hospital-acquired pneumonia, was associated with reduced costs and shorter hospital length of stay (LOS), but no significant difference of 30-day all-cause readmission rates. The above results justify the early use of NPPV for COPD exacerbations as a standard of care unless there are contraindications. COPD exacerbations also respond well to NPPV when complicated by pneumonia [28] or occurring in the setting of a DNI status [29–31] or postoperative or postextubation respiratory failure [32,33].

**Facilitation of Weaning in COPD Patients.** Some patients with COPD exacerbations require intubation because they are not candidates for NIV initially or fail a trial of NIV. Multiple controlled trials have demonstrated that NIV permits earlier extubation of these patients, even when they have failed multiple “T” piece weaning trials [34,35]. Early extubation to NIV increases eventual successful weaning rates, shortens the duration of ventilator use and hospital LOS, reduces the occurrence of nosocomial pneumonia, and reduces mortality. This approach should be considered whenever intubated COPD patients are failing spontaneous breathing trials, but it should be used with caution—only for patients who are otherwise appropriate candidates for NIV, can breathe without any assistance for long enough to permit initiation of NIV, can tolerate levels of pressure support deliverable by mask (i.e., inspiratory pressure <20
cm H$_2$O), and who are not a “difficult intubation.”

**Cardiogenic Pulmonary Edema**

Positive airway pressure has well-known therapeutic effects for patients with acute pulmonary edema. The increased functional residual capacity opens collapsed alveoli and rapidly improves respiratory system compliance and oxygenation. The increased intrathoracic pressure reduces transmyocardial pressure and has preload and afterload reducing effects, thus enhancing cardiac function of patients with left ventricular dysfunction who are afterload-dependent.

Multiple RCTs have demonstrated that noninvasive CPAP (10 to 12.5 cm H$_2$O) alone dramatically improves dyspnea and oxygenation and lowers intubation rates among patients with acute pulmonary edema compared with standard O$_2$ therapy [16,36,37]. Subsequent studies evaluating the efficacy of NIV (i.e., pressure support plus PEEP or BPAP) either compared with O$_2$ therapy or CPAP alone [38–40] have shown benefits similar to those previously demonstrated for CPAP. In one large RCT [40], CPAP and NIV performed similarly, both improving dyspnea scores and pH more rapidly than oxygen alone, but neither lowered intubation nor mortality rate (the primary outcome variable) compared to controls. However, the intubation rate for this study was slightly below 3% in all of the groups, including controls, suggesting that the enrolled patients were too mildly ill for a study of this size to detect significant mortality benefits. Meta-analyses of the RCTs on CPAP or NIV compared with O$_2$ therapy alone have detected the benefits described above, even showing a significant reduction of mortality with CPAP [41,42]. Meta-analyses comparing the two modalities show equivalency of NPPV and CPAP with regard to rates of intubation, lengths of stay, and mortality, and with no increase of the myocardial infarction rate attributable to NIV use. However, some studies have found that NPPV reduces dyspnea and improves gas exchange more rapidly than CPAP alone [43,44]. Therefore, by virtue of its greater simplicity and potentially lower cost, CPAP alone is often regarded as the initial noninvasive modality of choice for cardiogenic edema patients, but NPPV is substituted when patients remain dyspneic or hypercapnic. The strong evidence favoring the use of CPAP or NIV to treat CPE establishes either one as standard therapy for initial ventilatory assistance of appropriately selected CPE patients.

The success of noninvasive positive pressure to treat CPE has encouraged its extension into the prehospital setting. An emerging trend is to provide CPAP devices on ambulances for initial therapy of CPE. The experience thus far with this practice has been favorable. In a RCT, Thompson et al. observed an absolute reduction of 30% of intubation
rates (17 out of 34 patients, or 50% vs. 7/35 or 20%, unadjusted OR = 0.25 and CI = 0.09 to 0.73) and of 21% for mortality (OR 0.3; 95% CI 0.09 to 0.99) among CPE patients treated with CPAP compared to usual therapy with oxygen, including intubation and bag-valve-mask-ventilation when needed [45]. A subsequent pilot study reported an improved respiratory status for 12 DNI patients when managed with NPPV out-of-hospital by emergency medical services (EMS) professionals. Respiratory rate decreased from 34 to 27 per minute, \( p = 0.009 \), and pulse oximetry improved from 86% to 94%, \( p < 0.01 \), with only one intolerant patient [46]. A more recent RCT from Germany of 51 patients with CPE showed less frequent and shorter use of the ICU and a strong trend toward reduced rates of intubation among patients treated with NIV compared to standard \( \text{O}_2 \) therapy [47]. These studies suggest that outcomes of CPE patients can be improved by very early initiation of noninvasive positive pressure therapy in the field and adoption of this as a routine practice for EMS appears to be evolving.

**Immunodeficient Patients with Acute Respiratory Failure**

Based on studies showing that patients developing ARF with underlying immunodeficiency states such as human immunodeficiency virus and Pneumocystis pneumonia or post-transplantation have poor outcomes when treated with IMV [48] and RCTs demonstrating benefit of NIV over standard therapy for these patients [49], NIV has been suggested as a modality to be used early to avoid nosocomial infections, need for intubation and mortality. However, outcomes have improved among immunocompromised patients requiring IMV [50] and NIV was associated with worse outcomes than IMV for a RCT on patients with hematologic malignancies [51]. In addition, in a more recent RCT of 374 immunocompromised patients with “early” ARF (\( \text{PaO}_2 < 60 \text{ mm Hg on room air} \)), most with hematologic malignancies, NIV failed to lower 28-day mortality, intubation rate, ICU-acquired infection rates or lengths of ICU or hospital stay [52]. In the latter study, 40% of the \( \text{O}_2 \) therapy group used nasal high-flow therapy (HFT), which may have improved outcomes for the \( \text{O}_2 \) therapy group. The latter view is supported by a recent RCT comparing use of HFT to standard oxygen (SO) therapy or NIV in 310 immunocompromised patients with ARF culled from a larger study [53]. This study showed a 44% reduction of intubation rate and a 2/3 reduction of 90-day mortality rate when HFT was compared to NIV. These more recent findings have tempered enthusiasm for NIV as a therapy for ARF of immunocompromised patients. Although we await
more studies to better define its role for the management of ARF among immunocompromised patients, especially compared to HFT, NIV should still be considered for immunocompromised patients with early ARF and single organ system dysfunction. These patients should be closely monitored in an ICU and intubated without delay when the respiratory failure or underlying sepsis progresses in severity.
WEAKER INDICATIONS—NPPV IS AN OPTION

NIV can be used to treat ARF of other etiologies and in other settings, but the evidence to support these applications is weaker and use is optional but not necessarily recommended (Table 167.1).

Other Obstructive Diseases

Asthma Exacerbations

Retrospective cohort studies suggest that NPPV improves gas exchange and avoids intubation among patients with respiratory failure caused by asthma exacerbations [54,55]. However, there are only a few randomized trials supporting the use of NIV for this indication. In one, NIV improved the forced expired volume in 1 second (FEV₁) more rapidly and reduced the hospitalization rate compared with sham controls [56]. The second study [57] reported similar findings with “high” inflation pressures compared to lower pressures (IPAP and EPAP 8 and 6 cm H₂O and 6 and 4 cm H₂O, respectively—all lower than most other studies) or standard medical therapy. A third RCT from India enrolled patients with severe airway obstruction and respiratory distress (average FEV₁ 21% predicted, respiratory rate 36 per minute) to receive NIV or standard therapy with oxygen supplementation [58]. NIV tended to improve FEV₁ more for the first hour, with less salbutamol use and a shorter hospital stay (38 vs. 54 hours). However, the clinical significance of these differences is in doubt because, in both NIV and control groups, intubation rates were similarly low and there was no mortality.

Pollack et al. demonstrated that NIV is an acceptable way to deliver bronchodilator aerosol, showing a greater improvement of peak expiratory flow 1 hour after administration via a “bilevel” device than a standard nebulizer [59]. This and the above studies suggest that when NIV is used as an early treatment for asthma exacerbations, it allows more effective beta-agonist bronchodilatation. However, for most clinical situations, NIV is reserved for patients with “status asthmaticus,” that is,
those with severe airway obstruction who are not responding adequately to initial bronchodilator therapy, an application that is not yet supported by RCTs.

**Cystic Fibrosis**

Ideally, NIV is initiated for patients with cystic fibrosis when they develop chronic respiratory failure before an acute crisis arises. For patients with acute exacerbations of cystic fibrosis, NIV has been used mainly as a bridge to transplantation [60]. These patients may remain severely hypercapnic and require aggressive management of secretion retention, but NPPV permits avoidance of intubation and can sustain them for months while they await availability of donor organs.

**Hypoxemic Respiratory Failure**

Hypoxemic respiratory failure consists of severe hypoxemia ($\text{PaO}_2/\text{FIO}_2 < 200$), severe respiratory distress, tachypnea (>30 per minute), and a non-COPD cause of ARF such as ARDS, acute pneumonia, trauma, or acute pulmonary edema [61]. Some RCTs of hypoxemic respiratory failure patients have observed reductions in the need for intubation, shortened ICU lengths of stay, and even mortality in the NIV group as opposed to controls [62], but it is difficult to draw firm conclusions about individual diagnostic groups within this very broad category. A concern is that favorable responses in one subgroup, such as those with CPE, could obscure unfavorable responses in another, such as ARDS or pneumonia patients. Among studies examining subcategories specifically, Jolliet et al. found very high NPPV failure rates (>60%) in a cohort of patients with severe community-acquired pneumonia [63]. Confalonieri et al. [28] found that NIV was associated with lower rates of intubation, shorter ICU LOS, and lower 90-day mortality in a RCT of patients with severe community-acquired pneumonia. However, these benefits were seen only for the COPD subgroup—not for non-COPD patients. Thus, no convincing evidence supports the use of NIV over invasive ventilation for patients with severe community-acquired pneumonia lacking COPD, and although NIV remains an option for these patients, it should be used only for carefully selected and monitored patients, in a setting where prompt intubation is available to those who do not respond well within an hour of NIV initiation.

The situation with ARDS (which overlaps with severe community-acquired pneumonia) is quite similar, but few RCTs have been performed on the use of NIV for ARDS per se. One study used NPPV as a “first-line” therapy for ARDS, finding that the successful use of NIV was associated with much lower VAP and mortality rates than in NIV failures [64]. The
authors suggested that an initial simplified acute physiology score (SAPS) II of 34 or less and an improvement of PaO$_2$/FIO$_2$ to greater than 175 during the first hour of NIV therapy could be used to identify patients likely to succeed. However, it is good to remember that this was not an RCT and that only 15% of the total patients with ARDS (two-thirds were intubated prior to ICU admission) actually succeeded with NIV. A pilot RCT of 40 patients with “early” ARDS (PaO$_2$/FIO$_2$ >200 and ≤300) found that NIV reduced the need for intubation, the number of organ failures and tended to reduce mortality [65]. More recently, the FLORALI trial demonstrated advantages of HFT over NIV for patients with ARDS mainly due to pneumonia [66]. In this trial, NIV administered via a full-face mask was compared to high-flow nasal oxygen (HFNO) and SO in a three-way RCT [6] of patients with ARDS (PaO$_2$/FIO$_2$ <300). Although the main outcome, intubation rate, was not different for the whole cohort, it was significantly lower with HFNO for the subgroup with PaO$_2$/FIO$_2$ <200. Even more recently, an analysis of patients in the Large Observational Study to Understand the Global Impact of Severe Acute Respiratory Failure (LUNG SAFE) study showed that patients with more severe ARDS (PaO$_2$/FIO$_2$ <150) treated with NIV had a higher mortality than those treated with IMV (36.2 vs. 24.7, $p < 0.05$) [67]. These latter results raise serious concerns about the advisability of using NIV for patients with severe ARDS. Furthermore, both ICU and 90-day mortality were lower for the HFT group than the NIV group. However, another recent RCT [68] showed that among ARDS patients treated with NIV via a helmet interface, intubation (18% vs. 62%) and mortality (34% vs. 56%) rates were much lower than with a full-face mask (both $p < 0.001$). The conflicting results of the various studies make it difficult to make firm recommendations on the use of NIV for ARDS. Certainly, if NIV is used, it should be used early and observed closely in an ICU, with prompt intubation if there is lack of improvement or signs of further deterioration. In the meantime, further studies are needed to determine whether HFT is preferable to face mask NIV and how NIV via the helmet compares with HFT for the treatment of ARDS.

**Post-Trauma Respiratory Failure**

Flail chest or mild acute lung injury (ALI) are conditions that are posited to respond favorably to NPPV after traumatic chest wall injuries. Support for this view comes from retrospective studies such as that by Beltrame et al. [69], in which 46 trauma patients with respiratory insufficiency were treated with NIV and experienced rapid improvements of gas exchange and a 72% success rate, but burn patients responded poorly. More recently, a study that randomized thoracic trauma patients with
PAO$_2$/FIO$_2$ <200 to NIV or high-flow oxygen was stopped early after enrollment of 50 patients because of significant reductions of intubation rate (12% vs. 40%) and hospital LOS (14 vs. 21 days) in the NIV group [70]. These results support the use of NIV for hypoxemic respiratory failure in post-thoracic trauma cases, but it is good to remember that these were carefully selected patients.

**Extubation Failure**

The recurrence of respiratory failure after extubation of patients initially intubated for about of ARF is referred to as *extubation failure* and is associated with a high risk of morbidity and mortality (rates exceeding 40% in some studies [71,72]). NIV has been proposed as a way to avoid extubation failure if begun early for patients at risk for extubation failure, reducing the need for reintubation and improving outcomes. However, some earlier randomized studies [73] comparing NIV to standard O$_2$ therapy found no reduction of reintubation attributable to NIV. In fact, Esteban et al. even found a significantly increased ICU mortality for the NIV group [14]. These studies were limited by low enrollment of COPD patients (only about 10% of patients), and the increased mortality was thought to be related to a 10-hour delay in reintubations for the NIV group compared with controls. Two subsequent randomized trials [74,75] of patients deemed to be at “high risk” for extubation failure found that NIV reduced the need for reintubation and ICU mortality. Forty to fifty percent of patients of these trials had COPD or CHF and one trial focusing on patients with postextubation hypercapnia showed a significant reduction in the occurrence of postextubation respiratory failure as well as 90-day mortality for the group randomized to NIV compared to oxygen-treated controls [76]. These studies support the use of NIV for patients at high risk of extubation failure, particularly if they have COPD, CHF, and/or hypercapnia. However, based on the Esteban study, NIV to prevent extubation failure should be used very cautiously in at-risk patients who do not have these favorable characteristics because of the higher risk of NIV failure and its attendant morbidity and mortality. More recently, HFT has garnered interest as a therapy for postextubation patients. Hernández et al. randomized more than 600 patients at high risk of extubation failure to NIV or HFT, finding that reintubation rates were similar (22.8% for the HFT and 19.1% in the NIV group) as were other secondary outcomes including hospital LOS and mortality [77]. The authors concluded that HFT was noninferior to NIV and may “offer advantages” for at-risk postextubation patients, especially considering that adverse effects leading to withdrawal of therapy occurred among 42.9% of the NIV patients and none receiving HFT.
Postoperative Respiratory Failure/Insufficiency

Noninvasive positive pressure techniques, both CPAP and NPPV, have been used for postoperative patients in either of two ways: to prevent complications after high-risk surgeries or to treat frank postoperative respiratory failure. When used prophylactically after major abdominal surgery [78–80] or thoracoabdominal aneurysm repair [81], CPAP (10 cm H₂O) reduces the incidence of hypoxemia, pneumonia, atelectasis, and intubations compared with standard treatment. For patients with ARF following extubation after surgery, an earlier randomized study of post–lung resection patients showed reduced intubation and mortality rates for the NIV group compared with standard management [81]. A more recent larger RCT (293 patients) of respiratory failure occurring after various types –of abdominal surgery showed significantly fewer reintubations with NIV (33.1%) than SO (45.5%) as well as fewer health care–associated infections [82].

As with postextubation failure, interest has been mounting for a possible role for HFT in the postoperative setting. Stephan et al. [83] randomized over 800 postcardiac surgery patients who were at risk for postsurgical respiratory failure to NIV or HFT [82]. They found no differences in treatment failures, re-intubations or mortality (about 22%, 14%, and 5% to 6% respectively) between the groups and concluded that HFT is not inferior to NIV in this setting and therefore is a reasonable alternative.

The above studies strongly support the idea that CPAP and NIV should be considered to prevent and treat postoperative respiratory complications and failure for at-risk patients, and that HFT is an option but needs more evaluation for this role.

Patients with a DNI Status

NIV to treat DNI and palliative care patients has been controversial. Some argue that when patients are dying of respiratory failure, there is little to lose by trying NIV. Contrariwise, others counter that this is apt to add to patient discomfort and prolong suffering during a patient’s final hours. Prospective cohort series demonstrate that many DNI patients treated with NIV actually survive the hospitalization, depending on the diagnosis [31,84]. In one series, 43% of 114 such patients survived to hospital discharge, 75% of CHF patients, and 53% of COPD patients, whereas hospital survival for patients with pneumonia or an underlying
malignancy had hospital survival in the range of 25% [31]. The presence of cough, awake mental status, and hypercapnia also imparted a favorable prognosis. Thus, it is possible to identify, on the basis of the diagnosis and some simple clinical observations, patients with a better than even chance of surviving the hospitalization, and NIV could be used for these patients as a form of life support with the hope of “bridging” them through their acute illness. NIV can also be used for palliation of patients with a poor prognosis for survival of the hospitalization, with the possible aims of alleviating dyspnea or to prolong survival slightly so that the patient has time to settle affairs or say goodbye to loved ones. In the only RCT examining palliative use of NIV, Nava et al. [85] randomized 200 dyspneic patients with end-stage malignancies to NIV or oxygen, observing that NIV reduced dyspnea more rapidly and reduced the need for morphine. As recommended by a consensus statement by a Society of Critical Care Medicine task force on NIV, it is necessary for the patient, family, and caregivers to agree on these goals and to cease promptly if NIV seems to be adding to suffering (via mask discomfort, for example) rather than alleviating it [86].

Other Acute Applications of NPPV

Endoscopic Procedures

In separate randomized trials, CPAP alone (up to 7.5 cm H₂O) or NIV both improved oxygenation and reduced postprocedure respiratory failure for patients with severe hypoxemia undergoing bronchoscopy compared with those receiving conventional O₂ supplementation [87,88]. The evidence supports the use of NIV to improve gas exchange and reduce potential complications during fiber-optic bronchoscopy, especially when the risk of intubation is deemed high such as among immunocompromised patients or among those with bleeding diatheses. However, patients must be monitored closely and the caregiver team must try to minimize the risk of aspiration and be prepared to provide emergent intubation. NIV is also being used for other endoscopic procedures, such as placement of percutaneous gastrostomy tubes for patients with respiratory compromise due to neuromuscular disease and performance of transesophageal echocardiography [89,90].

Preoxygenation Before Intubation

A randomized trial of critically ill patients with hypoxemic respiratory failure showed that preoxygenation with NIV before intubation improved O₂ saturation during and after intubation and decreased the incidence of
O₂ desaturations below 80% during intubation [91]. This approach is promising but needs further evaluation before its routine use can be recommended. This also begs the question whether, if NIV improves oxygenation substantially, intubation could be avoided for some of these patients.
SELECTION GUIDELINES FOR NPPV IN ACUTE RESPIRATORY FAILURE

Determinants of Success/Failure

Selection of appropriate patients for NIV is critical for optimizing success and providing benefit. Knowledge of factors that predict success or failure is helpful in selecting good candidates for NIV. Such factors, compiled from previous studies, are shown in Table 167.2. In effect, the predictors indicate that patients who are most likely to succeed with NIV have incipient, milder respiratory failure than those who fail. This suggests that there is a “window of opportunity” for implementation of NIV when success is most likely. NIV should be started when patients have evidence of acute respiratory distress and increased acute physiology and chronic health evaluation II (APACHE II) scores, but not when patients are approaching respiratory arrest, have severe acidemia, high APACHE II scores, or are unable to cooperate.

APACHE II, acute physiology and chronic health evaluation II; ARDS, acute respiratory distress syndrome; NIV, noninvasive ventilation; SAPS
Predictors of success differ slightly between patients with hypercapnic and hypoxemic forms of respiratory failure. A chart to predict NIV failure of COPD patients identified pH < 7.25, respiratory rate ≥ 35, APACHE II score > 29, and Glasgow Coma score ≤ 11 as independent predictors of NIV failure [92], whereas a recent prospective multicenter study of NIV to treat patients with ARDS identified a SAPS II score of ≥ 34 and a PaO₂/FIO₂ ratio < 175 after the first hour as independent predictors of NIV failure [64]. In both analyses, the response to NIV after the first hour or two had more predictive value than baseline values.

For hypercapnic respiratory failure, a rise in pH and improving mental status within an hour or two of initiating NIV (presumably reflecting a drop in PaCO₂) predicts success, whereas, not surprisingly, a substantial early improvement of oxygenation bodes well for patients with hypoxemic respiratory failure. These observations highlight the importance of a “1- to 2-hour checkpoint” after which if the patient is not improving sufficiently, prompt intubation should be contemplated rather than risk further deterioration and the need for a riskier emergent intubation.

Selection Process

The selection of patients with ARF to receive NIV is based on criteria used in RCTs, and these are listed in Table 167.3. This is a simple three-step process, the first of which is to establish that the patient has a favorable diagnosis, ideally a condition like CPE or COPD, which is likely to respond to medical therapy fairly rapidly (a few days or less). Patients with weaker indications (i.e., acute asthma or pneumonia) can be tried on NIV but must be monitored very closely in an ICU, especially if they have risk factors for NIV failure. Patients at very high risk for NIV failure, such as those with sepsis and evolving multiorgan dysfunction, are generally best managed invasively rather than to delay needed intubation.

</tr>
</tbody>
</table>

II, simplified acute physiology score II; RR, respiratory rate.
Step two is to identify patients who need ventilatory assistance so that the modality is not wasted on patients who are too mildly ill to warrant ventilatory assistance. This is done on the basis of simple bedside observations of dyspnea, vital signs, and evidence of increased work of breathing (such as vigorous accessory muscle use). Arterial blood gas results showing acute-on-chronic CO₂ retention may be helpful, but needed ventilatory assistance should not be delayed pending availability of blood gas results. The third step is to exclude patients who have contraindications to NPPV and should be managed invasively (Table 167.4). Most of the contraindications are relative and judgment must be exercised when deciding whether patients have excessive secretions, medical instability, or uncooperativeness. Coma and severe obtundation are no longer considered absolute contraindications as long as they are related to hypercapnia. Patients with hypercapnic coma (Glasgow Coma Scale <8) have success and survival rates with NPPV that are equivalent to those of similar noncomatose patients [93].

Interfaces

Nasal Masks

Nasal masks are the most commonly used interfaces for outpatients with chronic respiratory failure because they are more comfortable than nasal prongs or oronasal masks, even if they are less efficient than oronasal masks at eliminating CO₂ [94]. In addition, they permit speech and expectoration and, with some practice, eating during use. Manufacturers offer numerous modifications of the nasal mask that fit into several basic categories.

Standard Nasal Masks

Standard nasal masks were first designed during the early 1980s to provide CPAP for obstructive sleep apnea (OSA) and consist of triangular clear plastic domes that fit over the nose (Fig. 167.1A). A soft, usually silicon cuff makes contact with the skin around the perimeter of the nose to form an air seal. These masks must be fit properly to minimize pressure over the bridge of the nose, which may induce redness, skin irritation, and occasionally ulceration. Forehead “spacers” are an adjustable joint often used to minimize pressure on the bridge of the nose. Various approaches have been used to enhance patient comfort, including an additional thin plastic flap or a baffle system to further reduce the strap tension necessary to maintain an air seal. Gel-containing seals, some that have heat-molding capabilities, may help to evenly distribute the pressure of the seal around the face.
Examples of interfaces used in the acute care setting. A: Standard disposable nasal mask for use with “bilevel” ventilator. The single circuit of these ventilators necessitates an in-line exhaust valve shown by arrow (Mirage Quattro mask, ResMed, San Diego, CA). B: Disposable full-face mask with chin “shelf” to keep mandible in position and reduce air leaking under the seal (Model RT040, Fischer Paykel, Wellington, NZ). C: Total Face mask that resembles snorkel mask and situates mask seal farther from nose and mouth (Performax, Respironics, Inc., Murrysville, PA). D: “Helmet” interface that consists of clear plastic cylinder that fits over entire head and fits with strap under axillae.

Nasal Pillows

Nasal “pillows” consist of small rubber cones that are inserted directly into the nostrils. By removing the sealing surface from the eyes, these reduce claustrophobia and permit use of eyeglasses. They also eliminate contact with the nasal bridge and are helpful for patients with nasal bridge irritation or ulceration caused by standard nasal masks. However, they can cause irritation of the nostrils, and some patients alternate between different types of masks as a way of minimizing discomfort. Nasal pillows are less often used in the acute care setting.
Oronasal or Full-Face Masks

The main advantage of oronasal over nasal masks is that they reduce air leaking through the mouth because they cover both the nose and mouth. Mainly because of this advantage, Kwok et al. found that the oronasal was significantly better tolerated than the nasal mask in the acute setting [95]. Air seals of oronasal masks are similar to those of nasal masks, using a thin membrane of soft silicon to enhance comfort and minimize air leaks. Oronasal masks have built-in valves to prevent rebreathing or asphyxiation in the event of ventilator malfunction, especially for “bilevel”-type ventilators. Because of concerns that vomiting into an oronasal mask could cause aspiration, these masks have straps that allow rapid removal. Some oronasal masks incorporate a “shelf” that fits under the chin to stabilize it, aiming to minimize air leaking under the seal (Fig. 167.1B). Compared with nasal masks, oronasal masks interfere more with speech and eating, have more dead space, and are less comfortable. However, because of their better initial tolerability and more efficient CO₂ removal than nasal masks, they are usually preferred to treat ARF.

The Total Face Mask (Respirronics, Inc.) is a larger version of an oronasal mask that seals around the perimeter of the face. It relocates the sealing surface from the nose and mouth to the perimeter of the face. It easily accommodates most facial shapes and sizes and can be rapidly applied by fastening just two Velcro straps behind the head. Although some patients find it frightening and refuse to try it, most find it comfortable and no more claustrophobic than standard oronasal masks (Fig. 167.1C). Two small RCTs comparing the Total Face Mask to a standard oronasal mask found no differences of outcomes between the masks, but one found that the Total face Mask was better tolerated and suggested that it could serve as an alternative for patients intolerant of standard full-face masks [96,97].

Helmet

The helmet (Fig. 167.1D) has been used primarily in Italy and has not yet been approved for use with NIV in the United States although a very similar device has been approved to avoid exposure of the lungs to hyperoxia in bariatric chambers. It consists of an inflatable plastic cylinder that fits over the head and seals around the neck and shoulders, sometimes secured by straps under the axillae. Some studies evaluating
its use for COPD patients show that it is more comfortable and reduces facial ulcerations compared with an oronasal mask [98], but a recent RCT showed equivalent responses and tolerance between the helmet and full-face mask, except the mask lowered dyspnea scores more rapidly [99]. In another recent RCT [68] on patients with ARDS, the helmet avoided intubation and reduced mortality compared to a standard full-face mask. To prevent rebreathing, high airflow rates are necessary, which render the helmet much noisier than oronasal masks (100 vs. 70 dB, respectively) [100]. Although the helmet has some potential advantages over the full-face mask and may be more efficacious than the full-face mask for ARDS patients [68], it is also noisier, costlier, and unavailable in many countries. Nonetheless, it has the advantage of avoiding contact over the nose and mouth and may serve as a useful alternative when patients are having trouble tolerating other masks.

**Oral Interfaces**

Oral interfaces consisting of a mouthpiece inserted into a lip seal that is strapped tautly around the head to minimize air leakage have been used to treat patients with chronic neuromuscular conditions for many decades. A commercially available oral interface was introduced more recently for the treatment of occasional patients with sleep apnea. These interfaces are not often used in the acute care setting, although some studies have had patients hold interfaces in their mouths to enhance their sense of control when initiating NIV [101].

**Headgear**

The straps used to hold interfaces in place are important for interface comfort and stability as well as for control of air leaks. The number of strap connections varies from two to five, depending on the mask. In general, the more connections, the more stable the interface, but discomfort and claustrophobia become concerns. Most straps use soft, elastic material fastened with Velcro, but abrasions can occur if the edges are too rough. Minimizing strap tension just to the point of controlling air leaks is important to optimize comfort.

**Ventilators for NPPV**

The specific ventilator chosen is probably not as important to NIV success as the settings selected or the skill of the care team. Many ventilator options are available, including critical care ventilators (designed mainly for invasive ventilation in the acute setting), ventilators designed especially for applications of NIV in the acute care setting,
“hybrid” ventilators that are designed mainly for use in the postacute setting or for sicker patients in the home, capable of providing pressure- or volume-limited ventilation invasively or noninvasively, and portable positive-pressure “bilevel” ventilators designed mainly for use in the home. The choice of ventilator depends mainly on availability, patient needs, and practitioner preferences. For example, patients with hypoxic respiratory failure may be very difficult to manage noninvasively and the sophisticated monitoring and oxygen delivery capabilities of a critical care ventilator may be preferred, whereas a patient with an exacerbation of COPD who is oxygenating adequately might do just as well with a small, portable, inexpensive bilevel device.

**Critical Care Ventilators**

The microprocessor-controlled ventilators currently used mainly for IMV in critical care units can be adapted for NPPV. These offer an array of volume-limited or pressure-limited modes and sophisticated monitoring and alarm capabilities. Advantages over “bilevel” positive pressure devices include the universal presence of O₂ blenders, accurate tracking of tidal and minute volumes, and a dual-limb circuit with an active exhalation valve that minimizes rebreathing (Fig. 167.2A). Most practitioners use the pressure support mode for NPPV with these ventilators because of enhanced comfort, combining it with PEEP [102,103]. Shortcomings of these ventilators when used to deliver NPPV include intolerance of air leaks that inevitably occur with NPPV, causing difficulty with triggering and cycling which sets off annoying alarms.
FIGURE 167.2 Examples of ventilators commonly used to deliver NPPV. A: “Critical care” ventilator that offers an “NIV” mode that permits multiple adjustments. May have trouble adapting to large leaks (Puritan Bennett 840, Covidien, Mansfield, MA). B: Typical “bilevel” ventilator designed mainly for home use but is capable of assisting ventilation in patients with acute respiratory failure as long as appropriate alarms are assured (S9 VPAP ST, ResMed, Inc.). C: Ventilator designed specifically for acute applications of NIV. Has oxygen blender and graphic monitoring screen (BiPAP Vision, Respironics, Inc.). D: Updated version of ventilator in (C). Offers internal battery for portability and improved graphic screen (V60, Philips Respironics, Inc., Andover, MA).

Most critical care ventilators now incorporate NIV modes that automatically improve leak tolerance and compensating abilities, disable nuisance alarms, and permit multiple adjustments including those to limit inspiratory time, thus enabling improved expiratory synchrony. These modes have undergone little evaluation in clinical settings, but bench studies demonstrated that most NIV modes of critical care ventilators work well to deliver set pressures or volumes unless there are large air leaks, in which case most of them require additional adjustments to maintain delivery [104,105]. One of the studies also examined synchrony of ventilated patients in a crossover study and found that NIV-dedicated ventilators synchronized slightly better than critical care and
transport ventilators using the NIV mode \[105\]. Masks and circuitry for
the application of NIV via critical care ventilators should not have the
built-in exhalation valves designed for use with single circuit bilevel
devices because these will increase air leaking and interfere with proper
function. Some mask manufacturers use blue coloration for plastic parts
of masks meant for use with critical ventilators so that they can be easily
identified.

**Bilevel Pressure-Limited Ventilators**

These devices were first conceived to enhance comfort for patients
requiring high CPAP to treat sleep apnea \[106\], but it rapidly became
apparent that they function as PS ventilators as well \[107\]. By virtue of
their air leak tolerance and algorithms to enhance synchrony in the face
of leaks, bilevel-type ventilators that deliver pressure assist or PS
ventilation are the most commonly used ventilators today for delivery of
NIV \[15\]. The prototype bilevel device was the “BiPAP S/T” (Respironics,
Inc., Murrysville, PA), introduced during the late 1980s, but numerous
versions are now available from many manufacturers (Fig. 167.2B).

Bilevel devices deliver two levels of positive pressure: preset inspiratory
and expiratory positive airway pressures (IPAP and EPAP, respectively).
The difference between the two is the level of inspiratory assistance, or
pressure support. Pressure support modes provide sensitive inspiratory
triggering and expiratory cycling mechanisms (usually by sensing
changes in flow), permitting excellent patient–ventilator synchrony,
reducing diaphragmatic work, and improving patient comfort \[107,108\].
Bilevel devices designed for home use are lighter (5 to 10 kg), more
compact (<0.025 m³), and have fewer alarms than critical care or
“hybrid” ventilators. Most have limited IPAP (up to 20 to 35 cm H₂O,
depending on the ventilator) and oxygenation capabilities and lack
alarms or battery backup systems. O₂ supplementation is provided via a
T-connector in the ventilator tubing or connector directly in the mask,
the latter providing a slightly higher FIO₂. Even at flow rates of 15 L per
minute, though, the maximum recommended by the manufacturer, the
FIO₂ is still only 45% to 50% \[109\], insufficient for many patients with
hypoxemic respiratory failure.

The BiPAP Vision and, more recently, its replacement the V60 (both
Phillips Respironics, Inc.) (Fig. 167.2C) were designed for both invasive
and noninvasive acute care applications, although they are used mainly
for noninvasive. Equipped with an O₂ blender, they can provide high FIO₂s and have more sophisticated alarm and monitoring systems than the home-based bilevel devices (including graphic screens). They also feature adjustable rise times (the time taken to reach target inspiratory pressure) and inspiratory time limits that can help with comfort and synchrony. Because of these features, these devices have been well-received for the administration of NIV at acute care hospitals. The V60 (Fig. 167.2D) also incorporates battery backup, improved graphics with a touch screen, and some additional modes.

Because they have a single ventilator circuit, rebreathing can occur during use of bilevel ventilators and can interfere with the ability to enhance CO₂ elimination [110]. The rebreathing can be minimized by using masks with in-mask exhalation ports, which are associated with less rebreathing than in-circuit valves [111], use of nonrebreathing valves, and EPAP pressures of 4 cm H₂O or greater, which ensure higher bias flows during exhalation [109].

Adjuncts to NPPV

Humidification may enhance comfort during NIV and is advised when NIV is to be used for more than a few hours. For the acute care setting, a heated humidifier is preferred over a heat and moisture exchanger because the latter adds to work of breathing [112] and may interfere with triggering and cycling. Also, with excessive air leaking, a heated humidifier lowers nasal resistance [113]. Nasogastric tubes are not routinely recommended as adjuncts to NPPV, even when oronasal masks are used, but small bore flexible nasogastric tubes can be used for feeding when necessary and do not interfere much with mask sealing.

Ventilator Modes

Although pressure support (or bilevel) is the most commonly chosen mode to deliver NIV, others might be considered. Average volume-assured pressure support (AVAPS) is available on the V60 bilevel device (Phillips Respironics, Inc.). It tracks recent delivered tidal volumes and automatically adjusts inspiratory pressure to achieve a target minute volume. This can be advantageous for hypoventilating patients as has been shown in obesity-hypoventilation patients [114], but no efficacy advantages over standard BiPAP have been shown for acute care settings.

Proportional assist ventilation, a mode that uses the inspiratory flow
signal and its integral, volume, to determine how much flow and volume assistance to provide to the patient, functions well as a NIV mode. It offers the potential advantages of enhanced comfort and synchrony [115]. Once again, studies have not been able to demonstrate improvements of efficacy over standard bilevel or pressure support modes in terms of reducing intubation or mortality rates. Neurally adjusted ventilator assistance (NAVA) uses the diaphragm electromyographic signal detected by an esophageal electrode to determine ventilatory assistance. Administered noninvasively, it improves synchrony compared to pressure support but without greater improvements in gas exchange or comfort [116].

**Initiation of NIV**

NIV is most often begun in the emergency department (ED) or ICU for acutely dyspneic patients who can become panicky when masks are strapped to their faces. Thus, unlike initiation of invasive ventilation with the patient heavily sedated or even paralyzed, initiation of NPPV requires skill on the part of the caregiver to rapidly gain the confidence of the patient and help them cooperate so that they can benefit from the technique. Explaining clearly what is happening and what to expect, using verbal cues like “try to let the ventilator breathe for you” and giving patients control by allowing them to hold the mask on their face can be quite helpful. Proper mask fit should be assured and the mask attached to the ventilator via tubing. Most practitioners start with PS ventilation using relatively low ventilator pressures (i.e., 8 to 10 cm H$_2$O for IPAP and 4 to 5 cm H$_2$O for EPAP) for at least several minutes to allow the patient to become familiar with the mask and airflow. It is then extremely important to increase the inspiratory pressure (and thereby the level of pressure support) to reduce respiratory distress and effort, targeting a respiratory rate in the low 20 s per minute and an increase in tidal volume to 6 to 7 mL per kg. Patients are often intolerant of higher pressures, especially initially, because of the sensation of burning in the sinuses or pressure in the ears, or because of the perceived effort of exhaling against an elevated pressure. Thus, the adjustment of inspiratory pressure becomes a titration, tailored for individual patients, balancing relief of respiratory distress and attainment of ventilatory targets against intolerance due to excessive pressures. Expiratory pressure is usually kept at 4 to 5 cm H$_2$O, but can be adjusted upward for patients who have difficulty triggering due to intrinsic PEEP, upper airway obstructions due to sleep apnea, or hypoxemia despite increases in FIO$_2$ to above 50% to 60%. L’Her et al. demonstrated that for patients with ALI that increases of PEEP during NPPV were quite effective for
improving oxygenation and increases of pressure support are effective for relieving dyspnea [117]. However, it is well to recall that if EPAP is increased during NIV, IPAP must also be increased by the same amount to maintain the level of pressure support and tidal volume.
MONITORING

Location for NIV

Because of the importance of prompt initiation to avoid further patient deterioration that could necessitate intubation, NPPV should be started wherever the patient comes to medical attention, as long as appropriate equipment and personnel are available. Once initiated, transfer to an appropriately monitored location becomes important. This depends on the patient’s need for monitoring as well as the unit’s monitoring capabilities and skills of the staff for managing NPPV. Assessment of a patient’s need for monitoring includes consideration of the severity of the respiratory failure as well as any comorbidities. When in doubt, a brief trial of NPPV withdrawal may be helpful. In one study of patients treated with NPPV in the ED for acute pulmonary edema or COPD, patients who remained stable during a 15-minute discontinuation trial were transferred to a regular ward and none subsequently required intubation [118]. NPPV is used on the regular wards of many hospitals because of the scarcity of ICU beds, but some guidelines have recommended that NPPV be applied only in the ICU because of concerns about patient safety [119]. Ozsancak Ugurlu et al. [120] reported that in eight Massachusetts, USA, hospitals, 42%, 37%, 18%, and 3% of patients were initiated on NIV in the ICU, ED, regular wards, and other wards, respectively. Of those on regular wards, 60% remained and 40% were transferred to the ICU. Those remaining on the wards succeeded with NIV in 82% of cases, exceeding success rates in the other units. These findings suggest that with proper training and availability of support personnel NPPV can be administered safely on regular floors for selected patients.

What to Monitor

Monitoring of NPPV shares similarities with that of IMV but also fundamental differences. Most importantly, subjective responses are critical to the success of NIV (Table 167.5). Alleviation of respiratory distress and good tolerance of the technique must be achieved without using large doses of analgesia and sedation as is commonly done with invasive ventilation. Thus, caregivers must observe patients closely for these responses and be prepared to make prompt adjustments as needed to maintain patient comfort and cooperation.

TABLE 167.5 What to Monitor During
### NPPV

**Subjective responses**
- Comfort
  - Mask related
    - Air pressure and flow related
- Dyspnea
- Claustrophobia
- Agitation
- Delirium

**Vital signs**
- Respiratory rate
- Heart rate
- Blood pressure

**Breathing effort**
- Accessory muscle use
- Paradoxical breathing

**Gas exchange**
- Continuous oximetry
- Baseline and 1–2 h arterial blood gases, then as indicated

**Synchrony**
- Triggering
- Expiratory asynchrony

**Air leaks**
- Mask seal
- Through mouth with nasal masks

**Secretion clearance**
- Cough effectiveness
- Quantity of secretions

**Development of complications** (see Table 167.6)

NPPV, noninvasive positive pressure ventilation.

Physical signs of increased respiratory effort should also respond promptly when NIV is administered properly, including changed of accessory muscle use and respiratory rate. Air leaks should be sought and minimized. These are universal with NIV, and with bilevel devices, the continuous leak through the exhalation device is intentional, of course, to minimize rebreathing. But leaks under the seal of the mask can be large and interfere with synchronization and efficacy.
Poor synchrony between the patient and ventilator, sometimes caused by excessive air leaking, patient agitation, ventilator maladjustment, or other factors, is common and contributes to NIV failure and must be identified and remediated [105]. Oximetry should be monitored continuously until the patient has stabilized and arterial blood gases should be drawn at baseline and after 1 to 2 hours of therapy to assure the desired gas exchange response. Tidal volumes of 6 to 8 mL per kg ideal body weight should be targeted. Tidal volume >9.5 mL per kg has been associated with NIV failure with 82% sensitivity and 87% specificity [121]. One important aspect of NIV monitoring is to determine early when patients are responding poorly to NIV so that the reasons can be reversed or failing that, the patient can be intubated promptly, avoiding undue delay and possible respiratory arrest with the emergent intubation and attendant risk of morbidity and mortality that entails.

Complications and Side Effects of NIV and Possible Remedies

NIV is successful for most patients and most adverse side effects are minor, but failure rates reported by studies representing “real-life” applications of NIV still approach 40% [15] and a knowledge of potential complications and ways of managing them can be helpful for minimizing NPPV failure rates. There are many possible adverse effects and complications, a variety of possible ways of categorizing them, and inevitable areas of overlap between the categories. For practical purposes, we distinguish between side effects related to the interface and those attributable to ventilator airflow and pressure, caregiver inexperience, or patient factors (Table 167.6).

| TABLE 167.6 Adverse Effects and Complications of NPPV and Possible Remedies |
|-----------------------------------------------|-------------------------------|
| **Interface related**                        |                               |
| Mask discomfort                               | Check size and fit. Readjust headgear. |
|                                               | Try different type.           |
| Skin ulceration, irritation                   | Readjust mask. Loosen straps. |
|                                               | Artificial skin prophylactically. |
| **Air pressure and flow related**            |                               |
Conjunctivitis  
Reseat mask. Check seal on nasal bridge.  
Artificial skin. Consider new mask type.

Gastric distension  
Lower pressure if possible. Simethicone.  
Observe or distension, consider nasogastric drainage.

Patient–ventilator asynchrony  
Eliminate leaks, treat agitation, assess for discomfort.  
Try lowering pressure support or limiting inspiratory time.

Rebreathing  
Use mask with in-mask exhalation valve.  
Use adequate EPAP (≥4 cm H₂O). Use ventilator with active exhalation valve.

Air leaks  
Reseat, readjust strap. Try different mask type. Chin strap if nasal mask. Lower pressure if possible.

### Caregiver related

| Inadequate or excessive pressures | Monitor more carefully. Adjust upward as tolerated. Assure adequate training. |
| Inadequate equipment | Initiate NPPV program, with full selection of masks. |

### Patient related

| Agitation, anxiety | Assure proper mask fit, ventilator settings. Reassure, consider sedation. |

### Major complications

| NPPV failure | Optimal monitoring to detect and address problems before they lead to failure. If failure not responding to appropriate measures, intubate promptly to avoid delay. |
| Respiratory arrest | Monitor at-risk patients in ICU or closely in stepdown unit. Intubate before arrest occurs to avoid attendant morbidity and mortality. |

EPAP, expiratory positive airway pressure; ICU, intensive care unit; NPPV, noninvasive positive pressure ventilation.

### Adverse Effects and Complications Associated with the Interface

### Mask Discomfort

Mask discomfort is one of the most common reasons cited for NPPV failure. It may reflect a poorly fitted mask, a patient’s difficulty accepting the interface chosen, excessively tight headstraps, a dyspneic patient’s discomfort at having foreign material strapped to their face, or other
factors. The clinician faced with a patient intolerant of NIV due to mask discomfort should quickly attempt to decipher the specific problem and correct it if possible. Often, inexperienced practitioners select masks that are too large and a trial with a smaller mask or a different mask type often helps. In the face of air leaks, reseating the mask and attempting to loosen the straps may help before resorting to tightening of the straps. As discussed earlier, an oronasal mask is usually the best initial mask choice, but some patients who are claustrophobic or expectorating frequently fare better with a nasal mask. Masks used in the acute setting are usually disposable after one use but some are reusable. They are relatively inexpensive compared to masks used for long-term applications of NIV, but it is still desirable to check that the mask selected is likely to fit (using a fitting gauge, for example) to minimize the need to dispose of multiple masks for each patient application. Noisiness can contribute to intolerance with some mask types such as the helmet [100].

Skin Irritation and Ulceration

Skin irritation and ulceration, mainly over the nasal bridge, is a less common complication of NIV as mask designs and skill at administering NIV has improved [15]. Contributors to NIV-related skin breakdown include excessive strap tension, mask type, poor mask fit, prolonged ventilation, high inspiratory pressures necessitating more strap tension to control leaks, hypersensitivity to mask material, and patient factors such as age and comorbidities such as congestive heart failure that can limit skin perfusion [122,123]. Facial structure and anatomical variation among patients also play a role. Prevention rather than treatment of skin breakdown is the best management strategy. This can be accomplished by optimizing mask fit while using the lowest effective positive pressures and strap tension and applying artificial skin to the affected area at the first sign of redness. Also, some newer mask types have softer, larger silicon sealing surfaces that minimize trauma to the facial skin. With these interventions, a significant nasal bridge ulcer should now be a rare event during NIV therapy.

Adverse Effects and Complications Associated with Airflow and Pressures

Nasal, Sinus and Ear Pain and Burning

Initiation of NIV is commonly associated with the sensation of nasal, sinus, and ear pain and burning. This is related to the patient’s lack of familiarity with the sensation of air pressure and flow and usually
subsides as the patient accommodates to the sensations. Using lower initial pressures and raising them gradually can help to minimize this problem as can making sure that any leak is minimized. Use of routine humidification can help with these side effects too.

Conjunctivitis

Conjunctivitis is another common adverse consequence of airflow during NIV. In this case, air leaks into the eyes due to a combination of high inspiratory pressure and incomplete mask sealing along the steep sides of the nose related to suboptimal mask fit and patient anatomic variations. This causes conjunctival dryness, irritation, erythema, and discomfort after a period of hours and may respond to lowered inspiratory pressures (when possible), reseating the mask or tightening the straps, or trying a new type or size of mask.

Gastric Distension

Gastric distension among patients receiving NPPV is common but is usually well tolerated. However, extreme complications such as gastric perforation and abdominal compartment syndrome have been reported [124,125]. A study of obese patients found that those receiving NPPV with an inspiratory pressure of 16 cm H₂O had more gastric distension than those breathing spontaneously [126]. The authors cautioned that the increased gastric air might raise the risk of aspiration. As stated earlier, the amount of gastric distension during NPPV is usually clinically insignificant, but if it causes excessive abdominal distension, discomfort, nausea, bowel distension on a KUB exam, or a compartment syndrome, then drainage with a naso- or orogastric tube is the next logic step. Gas dispersing agents like simethicone can be tried but are usually ineffective. Lowering the inspiratory pressure as much as possible can also help. But if there is a high risk of vomiting and aspiration or if nasogastric suctioning is unsuccessful, then intubation and other methods to decompress the bowel should be considered.

Patient–Ventilator Asynchrony

Patient–ventilator asynchrony is the lack of coordination between a patient’s own respiratory effort and the ventilator’s output. The consequences of this phenomenon can include inefficient gas exchange,
muscle fatigue, and ultimately, failure of NIV [127]. Asynchrony occurs frequently during NIV, mostly because of air leaks, rendering it difficult for the ventilator to sense the onset of patient inspiration and expiration, altered patient respiratory drive or agitation, ventilator mode, and inappropriately high inspiratory pressure for patients with COPD, contributing to ineffective triggering and cycling [128–130]. An observational study of three teaching hospital ICUs used an asynchrony index [the number of asynchrony events/(ventilator cycles + wasted respiratory effort) × 100] [127]. This study found that discomfort and air leaks were independent risk factors for asynchrony indices >10%. A follow-up study [131] found that an asynchrony index >10% occurred in 43% of patients and that double triggering and late cycling were the most common forms of asynchrony. Strategies to deal with asynchrony include minimizing air leaks, adjusting rise times and changing to timed modes (such as pressure control) to reduce the persistence of ventilator inspiration into patient expiration that occurs with bilevel modes [132], lowering pressure support when tidal volumes are large and breathing efforts fail to trigger the ventilator and giving sedation to control agitation or anxiety.

Rebreathing

Rebreathing has been a concern with bilevel ventilators in the past because of their single circuit design [133]. However, more recent studies have not demonstrated CO₂ rebreathing at levels deemed detrimental to patients, and rebreathing during NPPV has not been implicated in adverse patient outcomes [128,134] as long as the bias flow associated with expiratory pressures of 4 cm H₂O or greater are used flush CO₂ from the circuit to minimize rebreathing [129].

Air Leaks

Air leaks are universal during NIV because of its open circuit design. Some leaks are intentional as with bilevel ventilators, but air also leaks under the mask seal through the mouth and even into the gastrointestinal tract. Small leaks (<30 L per minute) are generally well tolerated as most ventilators compensate quite easily for them. However, large leaks (>60 L per minute) can have deleterious effects by interfering with ventilator assistance and synchrony, leading to increased work of breathing, fatigue, oxygen desaturations, and NIV failure. Leaks also contribute to patient
discomfort, contributing to conjunctivitis, sleep disruption, and dry mouth [130]. Air leaks are associated with improperly sized or sealed masks, loose or excessively tightened headstraps, the presence of facial hair, unusual facial anatomy, high inspiratory pressure settings, and the presence of surgical dressings or catheters that disrupt the seal. Nasal masks are commonly associated with mouth leaks, reported to occur in as many as 94% of patients receiving NIV for hypercapnic ARF and contributing to the majority of mask failures [135]. In a comparison study of four different NIV interfaces among patients with ARF, the mouthpiece had the largest leak, while there was no significant difference between the Total Face Mask, oronasal mask, or nasal mask [136].

Measures that can be undertaken to minimize leaks include careful mask selection and fitting, proper strapping to the face, removal of facial hair, use of chin straps with nasal masks, and chin supports (built into certain mask types) for patients using oronasal masks. Leak-compensating ability of the ventilator is another consideration for patients having frequent or large leaks. Most bilevel ventilators compensate quite well, but newer critical care ventilators that have NIV modes may need additional adjustments when large leaks are present [104].

Caregiver-Related Factors

Complications of NIV are sometimes related to caregiver decisions that inadvertently predispose to NIV failure. Most commonly, these include selection of inappropriate candidates with excessively high risk of failure, such as ALI/ARDS patients who are septic and developing multiorgan failure or elderly pneumonia patients with poor cough and excessive secretions. Inadequate attention to detail during initiation predisposes to failure, including neglecting to spend time with the patient to instruct and win their confidence or to properly fit or attach the mask. Failure to increase the inspiratory pressure after initiation is a common cause of NIV failure because the patient never receives adequate ventilator assistance. Inadequate monitoring, either because an unstable patient is never sent from a regular ward to the ICU or because caregivers neglect the early signs of deterioration, permitting a respiratory crisis to occur, are other common reasons for NIV failures. Caregivers need to know when to intubate patients who are not responding adequately to NIV before an emergency or respiratory arrest occurs, avoiding delays of needed intubation. There is no substitute for having a skilled and experienced multidisciplinary team for optimizing NIV success rates. Evidence from studies indicates that as caregivers gain experience with NIV, patient outcomes improve, or they can sustain the same favorable outcomes for sicker patients [16].
Multidisciplinary Approach

NIV works best when it is administered as part of a team effort. Ideally, this is achieved in a specialized unit such as an ICU or step-down unit where members can gain experience by working together over time. Although team members may have different roles depending on the country they work in, all of the roles must be adopted by one team member or another in order for optimization of NIV delivery. In North America, physicians must be skilled at selecting appropriate patients for NPPV and writing proper orders for its initiation. The respiratory therapist then fits and applies the interface and makes initial ventilator adjustments. Nurses then monitor the patient, notifying the physician and therapist when problems arise. Physicians and therapists should also participate in monitoring so that they can intervene with timely adjustments to the mask or ventilator settings or with intubation, when needed. Pharmacologists assist in choosing the type and dose of sedation or analgesia if deemed indicated, and nutritionists assist in assuring that nutritional needs are met. Physical therapists may also become involved to help with secretion removal or early mobilization. In other countries such as in the United Kingdom, physiotherapists assume many of the roles of the respiratory therapist, and in many countries in the developing world, physicians are responsible for initiation and application of equipment in addition to their other duties. Regardless of how the responsibilities are distributed, most programs favor using protocols and having periodic training in-services that document NIV competencies for their team members.

Patient-Related Factors

Patients vary enormously in their ability to tolerate NIV, and this is reflected by success rates. Patients who are cognitively impaired due to congenital or acquired processes, such as strokes, dementia, or delirium, are unlikely to tolerate NIV because they cannot comprehend the purpose and become agitated. Other patients panic when a mask is strapped to their face, either because of claustrophobia or because of their already heightened anxiety and distress due to their respiratory condition. These factors must be kept in mind when selecting patients or when deciding that NIV has failed. Some anxious patients respond to reassurance and being given control of the mask and others require an anxiolytic. Patients with dementia or delirium can sometimes be managed successfully with antipsychotics like haloperidol, risperidone, or quetiapine.

Sedation and Analgesia During NPPV
Judicious use of sedation may help to calm patients having difficulty cooperating with NPPV, but most clinicians are very cautious, using smaller doses, mainly by intermittent bolus, than they use in invasively ventilated patients. Most respondents to a survey of critical care physicians from North America and Europe indicated that they used sedation or analgesia in less than 25% of patients [137]. They registered concerns about blunting the drive to breathe of spontaneously breathing patients. North Americans were more apt to use benzodiazepines alone and Europeans opioids alone as their preferred initial choice.

Dexmetetomidine, by virtue of its short duration of action, intravenous administration allowing rapid adjustment of effect, analgesic as well as sedative properties, and lack of respiratory depressant effects, has been considered an attractive agent for use with NIV. In a RCT, Devlin et al. [138] showed no benefit of dexmetetomidine compared to standard intermittent benzodiazepines and opioids when started routinely at initiation of NIV. However, in another RCT, Huang et al. [139] showed reduced intubation and shorter lengths of hospital stay in a study of patients with CPE failing NIV due to intolerance or agitation. In Europe, remifentanyl use was also associated with a reduced need for intubation for small cohorts of patients failing NPPV [140,141]. These observations suggest that these short-acting infusion medications may have advantages as rescue agents, but have no role as agents to be used routinely at the time of initiation of NIV. More information from clinical studies is needed before recommendations for specific medications and doses can be made, but use of sedation or analgesia should be considered for patients at risk of failing NPPV because of agitation, apprehension, or discomfort.
SUMMARY AND RECOMMENDATIONS

NIV has assumed an important role for the management of patients with ARF in critical care settings. Epidemiologic studies indicate that use of NIV has increased substantially over the past 15 years throughout the world. Current evidence indicates that NIV is well supported for therapy of ARF associated with COPD exacerbations and acute pulmonary edema. NIV is an option in a number of other settings, including immunocompromised patients with early ARF, facilitation of weaning of intubated COPD patients and for COPD or acute pulmonary edema patients in other settings, such as postoperative, postextubation, and patients with a DNI status. Less evidence supports use for acute asthma, obesity hypoventilation with an exacerbation, cystic fibrosis, or neuromuscular disease, but NPPV would be a consideration for these patients. Most patients with ARDS or severe community-acquired pneumonia should not be treated with NIV, but exceptions include those with minimal secretions, stable otherwise and with only one or at most two organ failures, when experienced personnel and a closely monitored setting is available. Initiation of NIV requires a properly fit and tolerable interface and a ventilator that is appropriately managed. Patients should be placed in a location that permits adequate monitoring of their state of physiologic stability, and monitoring should pay particular attention to subjective factors including mask tolerance and adaptation to mechanical ventilation. Administration should be by a skilled and experienced multidisciplinary team. Achievement of these goals should lead to appropriate and safe administration of NIV with better overall patient outcomes and more efficient utilization of scarce ICU resources. A recent development has been the increasing use of HFT to treat patients with acute hypoxemic respiratory failure and ARDS, or during the postextubation and postoperative periods. Recent high quality studies indicate that HFT is noninferior to NIV in these settings and may even exceed NIV efficacy for some situations. HFT is better tolerated than NIV, is an effective oxygenator, and can improve the efficiency of ventilation, but more studies are needed to better define its role relative to NIV.

Summary of Major Recommendations

NIV should be considered the ventilator mode of first choice for ARF associated with COPD exacerbations \[27\] and acute CPE \[42\].
NIV is an option for early ARF of immunocompromised patients, and facilitation of extubation in COPD patients.
NIV can be considered to treat other patients with ARF such as those with asthma, exacerbations of cystic fibrosis, or obesity hypoventilation [15].

For patients who decline invasive ventilation, NIV can be used as a form of life support or to palliate, but should be discontinued when goals are not being achieved [86].

NIV should not be used routinely but very selectively and with close monitoring of patients with ARDS or pneumonia [64].

NIV should be administered in an ICU, ED, or stepdown unit under close and continuous monitoring until stabilization has occurred [119].

The full-face mask is the preferred initial interface for acute applications of NIV [95].

Increases of expiratory pressure can be used to treat hypoxemia and increases in pressure support reduce work of breathing [117].

Patient/ventilator asynchrony and air leaks can contribute to NIV failure and should be minimized [127].

When NIV is failing, intubation should not be delayed [14].

HFT may be considered as an alternative to NIV for selected patients with de novo, postoperative and postextubation hypoxemic respiratory failure, especially for patients intolerant of NIV [66,77,83].

A great deal of effort has been devoted to developing scientifically based strategies to achieve successful discontinuation of mechanical ventilation (MV), which is often referred to as “weaning.” This chapter focuses on practical elements important for discontinuation. These include: (a) understanding the problem, (b) predicting successful discontinuation, and (c) managing discontinuation failure.

UNDERSTANDING THE PROBLEM

Who are the Patients and What are Their Outcomes?

Patients with respiratory failure are the individuals who require MV support. Although there is an overlap, respiratory failure can be generally categorized into lung failure and pump failure. Lung failure is pure gas-exchange failure and is manifested by hypoxemia. It is commonly caused by the acute respiratory distress syndrome or cardiogenic pulmonary edema. Pump failure is synonymous with ventilatory failure and is manifested by hypercapnia and hypoxemia. It is commonly caused by central nervous system depression (e.g., overdose and anesthesia) or respiratory muscle fatigue or weakness.

Early in a course of MV, patients require ventilation because of the original disease process that created their respiratory failure. For those who recover quickly from that original insult, most (80% to 90%) [1–4] can have MV easily discontinued and be extubated. For this group, MV can be discontinued in 77% of patients within 72 hours of the initiation of MV [4]. This group is composed predominantly of postoperative patients,
patients with overdoses, and patients whose conditions cause pure lung failure that reverses rapidly. Later in their course of MV, the need for ventilation is usually less because of the original cause and more because of acquired barriers to weaning that have occurred during their hospitalization. Those patients, probably 10% to 20% of the total, are more difficult to wean from the ventilator and require additional attention. Data conflict regarding the impact of duration of MV on long-term survival. For example, 1-year survival for patients on MV for more than 21 days can be as high as 93% [5]. On the other hand, a recent study reported only a 56% 1-year survival and only 9% of those survivors were home without paid home care at 1 year [6]. Therefore, there is a great deal of improvement that can be realized for the treatment of this group of patients.

**What is Wrong with Patients on Prolonged Ventilator Support?**

Acquired barriers to weaning generally affect the balance between the supply and demand for ventilation. These usually act in one of four ways [7].

1. *Inadequate respiratory drive* may be caused by nutritional deficiencies, sedatives, central nervous system abnormality, or sleep deprivation.

2. *Inability of the lungs to carry out gas exchange effectively* may continue if the underlying cause of respiratory failure has not sufficiently improved, or if the patient has preexisting lung disease. Causes of this include but are not limited to pneumonia, airway diseases such as asthma and chronic obstructive pulmonary disease (COPD), and pulmonary edema.

3. There may be profound *inspiratory respiratory muscle weakness* and possibly *fatigue*. Examples of causes include pulmonary and nonpulmonary infections, sedatives, neuromuscular blocking agents, and cardiovascular impairment.

4. *Psychologic dependency* may be an additional factor [8].

Of these, the literature suggests that pump failure caused by inspiratory respiratory muscle fatigue/weakness [9] is primarily responsible for failure of discontinuation of MV in the majority of these patients [3,10,11]. *Muscle fatigue* occurs when a muscle loses its ability to generate force because of being worked against a load. *Muscle weakness* is when a rested muscle is unable to generate force [12,13]. Although
fatigue and weakness can be experimentally distinguished, this is not usually possible in the clinical setting. Therefore, the terms are often used interchangeably.

What Factors Lead to Respiratory Muscle Fatigue and Weakness?

The cause of inspiratory respiratory muscle fatigue is likely to be multifactorial. The major acquired barriers to weaning from MV are listed in Table 168.1. A few items deserve additional explanation.

**TABLE 168.1 Major Acquired Barriers to Weaning**

1. Inadequate mechanical ventilation
2. Cardiac disease
   a. Coronary ischemia
   b. Left ventricular dysfunction
3. Volume overload
4. Infection
5. Nutritional deficiency
6. Neurologic dysfunction
   a. Neuromuscular abnormalities (including critical illness neuromyopathy)
   b. Altered mental status (including sedative effects)

**Mechanical Ventilation**

Although it is assumed that one of the benefits of MV is that it rests the respiratory muscles, this may not actually occur [14]. The responses of mechanical ventilators to rapid changes in patient effort are often inadequate. This is particularly true for older-generation ventilators. Positive pressure MV may increase minute volume without decreasing respiratory muscle work. In part, this is because ventilators used in either the assist control or synchronized intermittent mandatory ventilation (SIMV) modes do not synchronize their output with that of the patient’s respiratory system. For extreme cases, the lack of synchronization causes patient effort to exceed that observed during unassisted breathing. Both SIMV and assist ventilation modes may cause problems in this regard.
Also, SIMV systems expose patients to increases in airway resistance during spontaneous efforts that occur between machine breaths. Continuous flow and demand valve systems have the potential for increasing the work of breathing. For instance, the continuous flow may not satisfy the patient’s inspiratory flow demands. Demand valve SIMV systems may increase the work of breathing because they require substantial effort by the patient to breathe spontaneously. In assist control mode the patient’s inspiratory muscles might work throughout the entire inspiratory cycle if tidal volume and inspiratory flow rate do not meet the patient’s inspiratory demands. If auto–positive end-expiratory pressure (auto-PEEP) is present (see Chapters 30 and 166), the patient may not be able to trigger the ventilator or may be able to capture it only intermittently while performing a prohibitively large amount of work, because he or she must drop airway pressure below the amount of auto-PEEP before triggering the ventilator. If these events happen, the patient’s diaphragm may develop an inflammatory injury that may not appear clinically for days afterward [15,16–18]. Paradoxically, although it is important to minimize the work of strenuous muscle activity while patients are receiving MV, it is also important to avoid prolonged muscle unloading because neuromuscular inactivity (“rest”) can lead to ventilator-induced diaphragmatic dysfunction [18].

Cardiovascular Disease

Cardiac dysfunction affecting weaning may be categorized as ischemic disease or pump failure, or both. Failure of the cardiovascular system may prolong MV for a variety of reasons. Pulmonary edema may impair gas exchange, and this may contribute to an increased work of breathing during spontaneous breaths. Poor cardiac performance may contribute to an inadequate supply of oxygen to the respiratory muscles, whereas an increased work of breathing conversely may provoke myocardial ischemia [19]. Although MV may adversely affect cardiac output by increasing intrathoracic pressure, thereby decreasing venous return and cardiac output, it is also possible that some cardiovascular patients cannot have MV discontinued because the ventilator exerts a beneficial influence on cardiac function (i.e., unloading the left ventricle in left ventricular failure) [20]. Prematurely withdrawing MV from these patients may lead to deterioration of cardiac function.

Nutritional Factors
Nutritional deficiencies may prolong the discontinuation process by leading to myocardial and respiratory muscle dysfunction [21]. Older studies suggested that an appropriate amount of nutritional support may improve the success rate of discontinuation of MV [22], but these were not definitive. Randomized controlled trials comparing high-fat versus conventional feeds and growth hormone versus placebo showed no change in discontinuation success [23].

Other Factors

Important other factors that contribute to respiratory muscle fatigue and weakness are sedation and excess lung water. Further discussion of these factors may be found in the section on Managing Discontinuation Failure.
PREDICTING SUCCESSFUL DISCONTINUATION

When is it Appropriate to Begin the Discontinuation Process?

There are no objective, rigorously generated data to determine the appropriate time to initiate weaning. Therefore, the authors recommend that clinicians consider a carefully monitored spontaneous breathing trial (SBT) when the following criteria, set forth in a national clinical practice guideline, have been met: (a) The underlying reason(s) for MV has been stabilized and the patient is improving, (b) the patient is hemodynamically stable on minimal-to-no pressors, (c) oxygenation is adequate (e.g., PaO$_2$/FiO$_2$ greater than 200, PEEP no more than 7.5 cm H$_2$O, FiO$_2$ less than 0.5), and (d) the patient is able to initiate spontaneous inspiratory efforts [24]. Because potentially harmful effects of suddenly having to take on the work of breathing occur early (albeit infrequently) during SBTs [25], patients should be closely monitored during the first 5 minutes. SBTs may be performed with a T-piece, with low-level pressure support ventilation (PSV), or with just a predetermined amount of continuous positive airway pressure (CPAP) using ventilators equipped with continuous flow internal circuits. There are no data that establish superiority of any of these approaches. There are also no data to show that attempts at starting the discontinuation of MV in this context lead to adverse consequences. On the contrary, screening patients daily to identify those who can breathe spontaneously can reduce the duration of MV and the cost of intensive care [26]. If the patient deteriorates or becomes distressed during this period of observation, MV should be restarted and a sufficient time given to allow the muscles to rest. That is generally done by performing the next trial the next day.

Predictive Indices for Total Discontinuation of Mechanical Ventilation (Weaning Indices)

A great deal of effort has gone into trying to find objective indices that will predict a patient’s ability to be safely removed from the ventilator [27]. These studies yield conflicting data. A collective task force of clinician investigators cofacilitated by the American College of Chest Physicians, the American Association for Respiratory Care, and the
American College of Critical Care Medicine developed evidence-based guidelines for weaning and discontinuing ventilatory support [24]. In their report, they evaluated the evidence for predicting success of weaning from MV [27]. A summary of their findings is as follows:

1. A large number of predictors have been found to be of no use in predicting the results of weaning.

2. A few predictors have been shown to be of some use, albeit inconsistent, for predicting discontinuation of the ventilator and successful extubation. Those include RR (RR) of less than 38 breaths per minute (sensitivity, 88%; specificity, 47%), a Rapid Shallow Breathing Index (RSBI) of less than 100 breaths/min/L (sensitivity, 65% to 96%; specificity, 0% to 73%), and an inspiratory pressure/maximal inspiratory pressure ratio less than 0.3. In addition, the combination of a RR of more than 38 breaths per minute and a RSBI more than 100 breaths/min/L appears to reduce the probability of successful extubation.

3. The ratio of airway pressure 0.1 second after the occlusion of the inspiratory port of unidirectional balloon occlusion valve ($P_{0.1}$) to maximal inspiratory pressure ($PI_{max}$) of 0.09 to 0.14 was highly predictive of successful extubation in two studies with a pooled Likelihood Ratio (LR) of 16.3 (>10 or <0.1 significant).

4. When LRs were calculated for RSBI, pooled results for a test predicting successful discontinuation showed a LR of 2.8; results for a test predicting failure of discontinuation showed a LR of 0.22. These results suggest mediocre accuracy [28].

Although clinical observation of the respiratory muscles during spontaneous breaths was initially thought to be reliable in predicting discontinuation failure, respiratory-inductive plethysmographic studies [29] cast this into question. Any time there is a substantial increase of load on the respiratory muscles, a change in the rate, depth, and pattern of breathing may be observed. Because these signs may also be manifestations of fatigue, it is useful to note them. If these signs never appear, successful discontinuation is likely. If they do appear, patients must be observed closely for further deterioration because discontinuation inevitably fails if these signs are owing to fatigue.
When is it Appropriate to Extubate the Patient?

Patients will succeed following extubation if they are able to pump air in and out adequately, and if they are able to maintain the patency of their airway. Therefore, a patient must (1) successfully pass an SBT in one or another weaning mode, (2) meet expectations that they will not suffer from upper airway obstruction, and (3) have a reasonable expectation of secretion clearance.

Weaning Modes

A patient can be placed on an SBT abruptly or gradually. An abrupt approach is generally referred to as an SBT method. Gradual approaches are achieved by either progressively reducing the RR or reducing the pressure applied. Clinically, those approaches are generally known as either “intermittent mandatory ventilation (IMV)” and “PSV” approaches to ventilator liberation. In addition, some degree of support for ventilation can be applied even after removal from the ventilator. In common terms, that is usually referred to as the “noninvasive positive pressure ventilation (NIPPV)” approach (see Chapter 167).

Results of randomized controlled trials comparing methods for weaning subjects from MV show that both SBT and PSV trials are superior to SIMV trials [30–32]. Therefore, we strongly discourage the use of SIMV for weaning. There are no convincing data to support the superiority of SBT or PSV compared to each other, and no data to support the practice of changing modes in patients who are not weaning successfully. The use of NIPPV should be limited to use for patients with CO₂ retention [33]. In other situations, NIPPV has not been shown to avoid reintubation in comparison to standard modes and can be potentially dangerous by delaying reintubation time [34]. Because we do not recommend SIMV trials, we only provide examples of SBT, PSV, and NIPPV protocols.

Spontaneous Breathing Trials. SBTs consist of the sudden, complete withdrawal of machine support. Patients are closely observed as they breathe humidified gas mixtures delivered by the T-shaped tube that is connected to the endotracheal or tracheostomy tube; alternatively, they can remain connected to the ventilator and be allowed to breathe spontaneously in the CPAP mode. In contrast to techniques that involve the gradual withdrawal of machine support, during SBTs the patient’s cardiopulmonary response patterns can be assessed without the confounding influence of machine settings. Although there is no generally agreed on standard of applying this method of discontinuation, most practitioners begin SBTs from assisted, not controlled, MV and assess the
Although CPAP is not universally used, the authors believe that it is physiologically sound to undertake SBTs in conjunction with CPAP irrespective of the underlying disease process. The addition of 5 cm H\textsubscript{2}O of CPAP mitigates the fall in end-expired lung volume that results from having eliminated glottic regulation of upper-airway resistance and flow with an endotracheal tube [35]. Furthermore, for patients with airflow obstruction, CPAP can substantially lower the work of breathing by counterbalancing end-expiratory system recoil pressures (i.e., intrinsic PEEP) and by shifting loads from inspiratory to expiratory muscles [36–38]. It is not likely that the 5 cm H\textsubscript{2}O of external PEEP will provoke hyperinflation by exceeding intrinsic PEEP.

An alternative mechanism by which CPAP can reduce inspiratory elastic work in airflow obstruction is by recruiting expiratory muscles during spontaneous breathing (SB). CPAP may result in exhalation below the new static equilibrium volume through the recruitment of expiratory muscles. Subsequent relaxation of the expiratory muscles inflates the lungs passively back to the new equilibrium volume. This may have the effect of unloading inspiratory muscles because the expiratory muscles do part of the inspiratory work. However, this mechanism is of limited value among patients with severe obstruction because low maximal flows prevent significant reductions of lung volume below static equilibrium volume.

In patients who continue to require MV only for oxygenation, CPAP may help maintain the benefits of improved oxygenation provided by PEEP without exposing the patient to the hazards of MV. It may also augment cardiac function during weaning.

**Spontaneous Breathing Protocol.** General guidelines are as follows:

1. When it has been decided that the patient is improving and stable, inform the patient that an attempt to remove MV will be made, why you believe he or she is ready, and what to expect. It is important to allow the patient to express fears whenever possible and to try to alleviate them [39].

2. Obtain baseline values and begin monitoring clinical parameters, such as pulse rate, RR, blood pressure, and subjective distress (e.g., have patients rate their dyspnea from 0 to 10), gas exchange (e.g., by pulse oximetry), and cardiac rhythm (e.g., by electrocardiographic monitoring). Record these values on a flow sheet that should be maintained and available. Arterial blood gases are generally not monitored during discontinuation trials.
3. Ensure a calm atmosphere by having the nurse, respiratory therapist, or physician remain at the bedside to offer encouragement and support.

4. Avoid sedation to ensure maximal patient effort. In most cases an interruption of continuous sedation is performed to coincide with the SBT.

5. Whenever possible, let the patient sit upright in bed or in a chair.

6. Fit the patient’s endotracheal tube with a T-tube connected to a heated nebulizer with an inspired oxygen concentration 10% greater than that prevailing during the previous course of MV. Ensure that the T-tube flow exceeds the patient’s peak inspiratory flow and that the inhaled gas is constantly humidified. If CPAP is being used, the T-tube setup becomes unnecessary and the ventilator system tubing is used.

7. Continue the trial to completion unless the following conditions develop:
   a. New onset diaphoresis
   b. New onset arrhythmias
   c. Systolic BP >180 mm Hg, or a change (increase or decrease) of ≥20% of the original systolic value or a new requirement for vasopressors.
   d. Heart rate >120, or a change (increase or decrease) of >30 beats per minute
   e. SaO₂ <90%, FiO₂ >0.6
   f. If a blood gas is obtained, pH <7.30; PaO₂ <60 mm Hg; SaO₂ <90%; rise in PaCO₂ of more than 10 mm Hg.
   g. Unstable pattern of ventilation
   h. RR <8 breaths per minute, >35 breaths per minute for >5 minutes, change of >50% of original RR, or a RSBI (f/V₂) >100
   i. New onset altered mental status
   j. Signs of respiratory muscle failure including new onset use of accessory muscles of breathing or thoracoabdominal paradox
   k. Subjective discomfort of the patient with dyspnea or new pain rated as greater than 5/10
   l. Failure as determined by the subjective assessment of the nurse, physician, or the respiratory therapist
If the trial is terminated, place the patient back on the previous MV settings. With few exceptions, such as patients recovering from general anesthesia or sedation with or without muscle paralysis, the authors usually do not have their patients undergo more than one (failed) discontinuation trial in any 24-hour period. This practice is supported by the work of Esteban et al. [40], who showed that twice-daily SBTs offered no advantage over once-daily trials. Moreover, the inspiratory effort associated with a failed weaning trial may be sufficient to induce muscle fatigue that may not recover [40], unless it is followed by an extended period of rest.

If a patient has no underlying lung disease, has been on MV for only a short time (e.g., less than 1 week), appears to be tolerating SB without dyspnea for 30 to 120 minutes, and maintains an adequate level of oxygenation, extubation may be performed after considering whether the patient is at risk of postextubation upper airway obstruction or not being able to clear secretions.

**Pressure-Support Ventilation Trials.** PSV discontinuation decreases MV gradually, making the patient responsible for a progressively increasing amount of ventilation. Although it is commonly assumed that PSV can be decreased to a low level (e.g., 5 to 7 cm H$_2$O) that compensates for endotracheal tube and circuit resistance, there is no simple way of predicting the level of PSV that compensates for this resistance.

PSV has become a popular mode of discontinuing MV for adults. In the PSV mode, a target pressure is applied to the endotracheal tube that augments the inflation pressure exerted by the inspiratory muscles on the respiratory system [41]. As the lungs inflate, inspiratory flow begins to decline because airway pressure and the inflation pressure exerted by the inspiratory muscles are opposed by rising elastic recoil forces. When inspiratory flow reaches a threshold value (that differs among vendors), the machine switches to expiration [42]. The popularity of PSV is based on the premise that discontinuation from MV should be a gradual process (meeting the definition of “weaning”). In addition, proponents of PSV over SBTs argue that the work of unassisted breathing through an endotracheal tube is unreasonably high and could lead to inspiratory muscle failure among susceptible patients [43]. For example, it has become popular to assume that PSV is an effective means to overcome the resistance of endotracheal tubes. However, this is conceptually incorrect because airway pressure during PSV does not vary with flow. Furthermore, a reduction of pulmonary resistance is not demonstrated after extubation [44], and the work of breathing may actually increase
This suggests that, at least immediately after extubation, most patients manifest upper-airway resistance that is, in effect, equal to or greater than that of an 8-mm internal diameter endotracheal tube.

Enthusiasm for using PSV for all patients should be tempered by knowledge of its potential adverse patient–ventilator interactions. For example, elderly patients and even healthy individuals [46] are susceptible to PSV setting–induced central apneas. The mechanism appears to be intermittent hypocapnia, resulting from the uncoupling of tidal volume from inspiratory effort. Problems may arise when the physician feels compelled to rest susceptible subjects with PSV at night. Unless sufficiently high IMV backup rates are used in combination with PSV, the mechanical inhibition of inspiratory drive may result in apneas that trigger ventilator alarms and cause arousals and sleep fragmentation that can prolong the discontinuation process.

**Pressure Support Protocol. General guidelines are as follows:**

1. Repeat steps 1 through 5 of the SB protocol.

2. Switch the MV mode from volume-cycled breathing with assist or SIMV modes to PS, or, if the patient is already on PS as a ventilatory mode, decrease the amount of PS.

3. For patients who have received prolonged ventilator support (e.g., greater than 21 days), patients with neurologic diseases, or patients who have recently failed extubation, begin PS at a pressure of 25 cm H\(_2\)O if switching from another ventilatory mode, or less than the amount previously used during PS ventilation, and increase the fraction of inspired oxygen by 10%. Decrease airway inflation pressure slowly. If the patient fails to assume the increased work of breathing at a lower pressure, increase the pressure to the previously tolerated level and then higher, if necessary, until the patient is stable again. Then wait for 24 hours and begin the process again.

4. For patients who have no underlying lung disease and who have been on MV for only a short time (e.g., less than 1 week), PS can be set at 7 cm H\(_2\)O. If this pressure is well tolerated for 2 hours, the patient should be assessed for extubation [47].

**Noninvasive Positive-Pressure Ventilation as a Mode of Discontinuing Mechanical Ventilation.** A comprehensive description of NIPPV can be found in Chapter 167. Patients can receive this form of ventilation using either a ventilator specifically designed for noninvasive positive-pressure or an intensive care unit (ICU) ventilator, using PS mode plus PEEP. Ventilation can be delivered with a nose or
face mask or, outside the USA, a helmet. Current literature indicates that the use of noninvasive ventilation as a “rescue” therapy for patients who are experiencing respiratory failure following extubation is ineffective for preventing reintubation [48]. Noninvasive ventilation may be an effective strategy for reducing reintubations and mortality among patients with chronic CO$_2$ retention when used routinely early after extubation [49].

**Noninvasive Positive-Pressure Ventilation Protocol.** General guidelines are as follows [50]:

1. Repeat steps 1 through 5 of the SB protocol.

2. Extubate the patient, apply a nose or face mask designed for NIPPV, and begin assisted breathing. Continuously adjust the ventilator settings (see Chapter 167) according to patient comfort, the presence of air leaks, and monitoring.

3. In between periods of 1 to 2 hours of SB with supplemental oxygen, intersperse intermittent periods of ventilation for 2 to 4 hours at a time. Then, gradually increase the duration of the SB periods as tolerated by the patient (e.g., monitor RR, gas exchange, and cardiorespiratory parameters and dyspnea).

4. When the period of SB spans the entire day and the patient is only receiving nocturnal ventilation, consideration should be given for discontinuing NIPPV.

**Unconventional Modes of Discontinuing Mechanical Ventilation**

A variety of unconventional techniques have been tried for discontinuing MV. These include inspiratory strength training [51], adaptive support ventilation [52], biofeedback [53,54], automatic tube compensation [55,56], and proportional assist ventilation. None of these techniques are supported by adequate evidence to justify recommendation as routine care.

Uncontrolled reports suggest that inspiratory muscle strength training [57] may be useful for preparing patients who are on prolonged ventilatory support for discontinuation. This method is thought to serve as a means of respiratory muscle endurance training; it is implemented by having patients perform low-repetition, high-resistance SB exercises.
During adaptive support ventilation [52], an automatic microprocessor-controlled mode of MV ensures the delivery of preset minute ventilation. It does this by continuously adapting to the patient’s respiratory activity. Adaptive-support ventilation was developed in an attempt to automatically discontinue patients from MV by feedback from one or more ventilator-measured parameters.

Biofeedback, the detection and transmission back to the patient of some biologic functions that he or she cannot detect, may be helpful for selected patients [53,54]. For instance, by displaying respiratory volumes on bedside oscilloscopes and having patients make voluntary efforts to push volume tracings beyond limits taped on the screen, Corson et al. [53] allowed two patients with spinal cord lesions—one with a sensory level at C6 who lacked proprioceptive afferents from the chest wall—to gain control over their breathing. These authors assumed that the repeated practice of reaching the criteria of feedback increased the strength of the diaphragm and inspiratory muscles and may have had the net effect of enabling the medullary center to reinstate automatic breathing.

Automatic tube compensation (i.e., a means of resistive unloading during ventilator-assisted SB by compensating for the pressure drop across the endotracheal tube) has been best studied. Compared with SBT in a randomized controlled trial, there was no clear difference in clinically significant outcomes [57].

Proportional assist ventilation (PAV) is a mode of partial ventilatory support in which the ventilator applies pressure in proportion to the inspiratory effort [58]. This has potential value in liberating patients from MV. The theoretical advantage is that the support applied seems to coordinate well with the patient’s own respiratory effort, thereby simulating SB but with less respiratory work. No studies have demonstrated a clinical advantage of this method over conventional methods.

How Long Should Discontinuation Trials Last?

The question regarding length of discontinuation trials has not been definitively answered. Therefore, the duration depends on the patient population, the weaning mode, and local practice. With respect to SBTs, a number of authors have set a maximum limit of 2 hours [25,30,47,59–62] and have extubated patients who were deemed stable by clinical, respiratory, and hemodynamic parameters. With respect to PSV trials, some have recommended that stable patients need only be on PSV at a setting of 5 to 7 cm H₂O for 2 hours before extubation. With these guidelines, reintubation rates range from 13% to 23% [30]. With respect to SBTs, other authors have found no difference in success of
discontinuing MV when 30-minute and 2-hour trial intervals have been compared [61,62]. Nevertheless, because reintubation has been shown to be associated with a significantly greater risk of (a) in-hospital mortality, (b) ICU and hospital length of stay, and (c) transfer rate to a long-term care or rehabilitation facility [60], and because it is prudent to minimize the need for reintubation, we recommend the following:

The authors prefer SBTs over other modes because they are the most direct way to assess the patient’s performance without ventilatory support.

Consider extubating patients who have well-tolerated SBTs of 30 to 120 minutes, with the following exceptions [63,64]: (a) patients with a tracheostomy who meet the definition of being on prolonged MV (i.e., at least 21 days for at least 6 hours per day), (b) neurologic patients who are predicted to have difficulty clearing their respiratory secretions, and (c) patients who have had to be reintubated after the recent discontinuation of MV. It is our practice to observe these patients breathing spontaneously for 2 to 24 hours before considering extubation. Factors discussed below related to upper airway obstruction and secretion clearance play a major role in determining the length of an SBT.

Discontinuation should be performed using a clinical practice guideline that clearly defines responsibilities and empowers nurses and respiratory therapists to act within their scope of practice.

**Upper Airway Obstruction**

Patients at the highest risk of postextubation upper airway obstruction are those who have been on prolonged MV, are female, who have had repeated or traumatic intubations, or who have been intubated with a larger endotracheal tube size [65,66]. One method of assessing for the presence of upper airway obstruction during MV is the cuff-leak test. It is performed by comparing the exhaled volumes before and after the balloon of the endotracheal tube has been deflated. Although one study [67] showed that a cuff leak of less than 110 mL measured during assist-control ventilation within 24 hours of extubation identified patients at high risk of postextubation stridor, other studies have not [68]. Although the concept of measuring cuff leak is intuitively appealing, the benefits are not clearly identified, and the process and even the actual values for decision-making are not broadly agreed upon. Values of 110, 130, and 140 mL have all been published, and other studies used an approach of auscultation to detect leak. In addition, the appropriate course of action to take for an abnormal test is not defined. Some authors suggest treatment with steroids, some suggest delay of extubation, and some
advocate having persons with advanced airway skills present for the extubation. Because we are unable to scientifically determine which patients should have a test, how we would conduct the test and what would constitute an abnormal result, and what we would do with an abnormal value if we had one, we do not advocate routinely performing or basing decisions on the results of a cuff-leak test. A provider may consider using a cuff-leak test for specific patients to gain a general appreciation of the airway status in a high-risk patient [69–71]. We also do not routinely administer systemic steroids to prevent postextubation stridor because of the inconsistent benefits reported by studies, and the uncertain timing of extubation encountered in clinical practice, which could potentially lead to extended courses of steroids with their associated side effects [72].

**Secretion Clearance**

Patients may also fail extubation because they are unable to clear their secretions. A prospective observational study [73] showed that the strongest predictors of extubation failure in patients who passed an SBT were (a) poor cough defined as a cough peak flow measurement of less than 60 L per minute, (b) secretion volume of 2.5 mL per hour or greater, and (c) poor mentation as determined by the inability to complete any of the four following tasks on command: open eyes, follow observer with eyes, grasp hand, and stick out tongue. In this series, reintubation took place in 12% of patients when one of these predictors was present and 80% when all were present.

Once extubation has taken place, the authors proceed cautiously before instituting feedings by mouth. Because there is no clinically reliable way of assessing the adequacy of swallowing at the bedside and picking up “silent aspiration,” a formal swallowing evaluation (e.g., speech pathology consult and video fluoroscopic evaluation of swallow) should be considered for patients at increased risk of aspiration before resuming oral feedings. Although it is commonly appreciated that older age, debilitation, sedation, oral or nasal enteral feeding tubes, history of dysphagia, acute stroke, cervical spine surgery, muscle weakness, and/or tracheostomy are risk factors for aspiration, it is less commonly known that endotracheal intubation carries the same risk [74,75]. After extubation, swallowing difficulties exist among up to 50% of patients for 1 week, even when intubation has been of short duration, and the patient is awake and not seriously ill. In awake, postsurgical patients evaluated for aspiration following extubation, 50% of those who aspirated did so immediately when fed, whereas 25% and 5% aspirated when tested 4 and 8 hours later, respectively.
The authors’ general approach to managing patients who have failed to have MV discontinued is based on three tenets: (a) protocol-based weaning yields superior outcomes when compared to nonprotocolized weaning; (b) SBT or PSV trials should be performed once daily; and (c) barriers to weaning are clinical conditions that promote muscle fatigue and weakness. Interventions that address and reverse these barriers are keys to successfully liberate patients from MV.

Protocol-Based Weaning

Multiple randomized controlled clinical trials [25,76] and nonrandomized controlled trials [77] have shown overwhelming advantages for clinically significant outcomes (e.g., decreased duration of MV, reintubation rates, ICU and hospital LOS) generated by the use of protocol-directed discontinuation implemented by nonphysician health care providers. These findings have been supported by a recent meta-analysis [78]. That report identified that reduced duration of MV, discontinuation duration, and ICU length of stay can be realized with use of standardized discontinuation protocols. These improvements are more consistent and of a larger magnitude than those generated by virtually any other intervention related to liberation from MV. Therefore, the authors strongly recommend that institutions employ protocols to guide interprofessional discontinuation efforts rather than wean by individual physician discretion.

Once-Daily Attempts at Liberation from Mechanical Ventilation

On the basis of multiple randomized controlled trials of methods for discontinuing patients from MV [32], the authors recommend that once-daily SBT or PSV trials be used as the discontinuation mode of choice. Because duration of MV is primarily determined by admitting diagnosis and degree of physiologic derangement [79], there does not appear to be anything to be gained by switching from one mode to another when the discontinuation process is prolonged. Switching to another mode and waiting to see the response directs the attention away from addressing factors that cause inspiratory muscle fatigue/weakness that we believe are the most important reason why patients are on prolonged MV.
Addressing Factors that Perpetuate Respiratory Muscle Fatigue

Respiratory muscle fatigue is almost always multifactorial in etiology (Table 168.2). Therefore, clinicians should systematically consider ways to increase muscle strength and decrease muscle demand.

SIMV, synchronized intermittent mandatory ventilation; ICU, intensive care unit

The following measures should be considered to increase respiratory muscle strength:
1. Reverse malnutrition \[22\] and correct deficiencies of electrolytes.

2. Improve cardiovascular pump function and minimize cardiac ischemia \[20\]. Poor cardiac performance may contribute to an inadequate supply of oxygen to the respiratory muscles.

3. Attempt to minimize the use of sedative drugs whenever possible. Whereas daily interruption of sedation compared to continuous infusions significantly decreases duration of MV and length of stay in a medical ICU \[80\], a more aggressive approach is to eliminate the use of continuous sedation and/or all sedation. One study of no sedation reported an increase of ventilator free days and a reduced ICU and hospital length of stay without any change in mortality \[81\]. Further study is needed to confirm these results. To assist in managing sedation, clinicians are encouraged to use validated and reliable monitoring scales such as the Richmond Agitation-Sedation Scale \[82\]. Pairing sedation and ventilator weaning protocols may yield a mortality benefit \[83\].

4. Efforts to reduce sedation overlap with attempts to reduce the incidence of delirium. A major component of these efforts is to reduce or eliminate the use of benzodiazepines by ventilated patients. Some authors have advocated for the use of dexmedetomidine for ventilated patients to reduce the incidence of delirium that leads to increased sedation. A randomized trial demonstrated reductions of the incidence of delirium and time on the ventilator seen with dexmedetomidine in comparison to midazolam \[84\]. Other components of delirium prevention include appropriate pain control, lighter levels of sedation, preservation of sleep-wake cycles, cognitive stimulation, and early mobilization among others.

5. Consider and evaluate for the possibilities of myopathy and polyneuropathy \[85\] and drug-induced neuromuscular dysfunction (e.g., neuromuscular blocking agents and antibiotics, especially aminoglycosides) \[86,87\]. Critical illness polyneuropathy and myopathy are major causes of persistent respiratory failure \[88\].

6. Mobilize patients to the maximum of their tolerance and initiate physical and occupational therapy early in their course. A protocol of early physical and occupational therapy combined with daily interruption of sedation demonstrated significant improvements in return to baseline functional status at hospital discharge and for the number of ventilator free days in the first 28 days of hospital stay \[89\].

7. Have the patient sit up to take advantage of gravity and maximize diaphragm function.

8. Reverse hypothyroidism.
Previously some authors have suggested improving respiratory muscle contractility with various interventions including elimination of hypercapnia by increasing excretion of compensatory bicarbonate ions. However recently a randomized, placebo controlled trial of acetazolamide failed to show any improvements in mortality, duration of MV or other clinically relevant end points [90]. Therefore, we do not recommend that approach.

Consider that progesterone may act as a respiratory center stimulant [91] in patients who take few or no spontaneous breaths despite a lack of sedative drugs. The effect of 20 mg of medroxyprogesterone acetate three times per day should begin within 2 days and be maximal within 7 days. This is a controversial therapy. Many believe the additional respiratory center stimulation may be inappropriate and precipitate worsening muscle fatigue.

The following measures should be considered to decrease respiratory muscle demand:

1. Maximize treatment of systemic disease (e.g., infection, acute and chronic uremia) to decrease metabolic requirements and mitigate production of chemical mediators with adverse effects on muscle.

2. Give bronchodilators for conditions associated with increased airway resistance (see Chapters 172 and 173); discontinue beta-blockers in asthmatic patients.

3. Use diuretics to reduce lung water in patients with pulmonary edema. Closely monitor renal function and serum sodium to avoid precipitating renal failure and hypernatremia.

4. Evaluate for compromised cardiac function. Echocardiography and assessments for myocardial ischemia such as 12 lead ECG or ST segment monitoring can diagnose underlying cardiac disorders. The increased work of breathing during discontinuation may steal oxygen from the heart as well as other organs and precipitate ischemia and heart failure among susceptible patients [20,92,93].

5. For average-size adults, endotracheal tubes less than 8 mm in internal diameter significantly increase airway resistance, although it is unlikely that tube size adversely affects the discontinuation process unless the tube is prohibitively small (i.e., <6 mm). If an effect on
weaning success is suspected, replace the smaller tube with one with a larger internal diameter.

5. Consider CPAP for patients with marginal cardiac function. It may provide support for a failing heart by decreasing left ventricular preload [20,94].

7. Consider that the ventilator is increasing the work of breathing, and make adjustments [14]. Potential factors include (a) the appropriateness of the sensitivity/responsivity of the ventilator triggering system, (b) whether the ventilator flow pattern is synchronized with the patient’s demand, (c) the appropriateness of the ventilator settings to avoid dynamic hyperinflation, (d) considering usage of extrinsic PEEP to overcome an increased triggering threshold load from PEEP, and (e) changing a heat and moisture exchanger to a heated humidifier to overcome the increased dead space and resistance of the exchanger [95].

8. Evaluate for overfeeding. Excess total caloric intake, but not disproportionate carbohydrate intake, may precipitate increased CO₂ production and respiratory acidosis for patients unable to increase their alveolar ventilation adequately when compensating for increased CO₂ production [96]. The treatment for this is to reduce caloric intake.

9. Consider performing tracheostomy when patients are predicted to require prolonged MV. Tracheostomy may improve patient comfort and mitigate the need for more sedation, decrease airway resistance, decrease ventilator-associated pneumonia, and decrease duration of MV. Although the best time to perform tracheostomy is not known, a recent meta-analysis of early versus late tracheostomy found improvements in ventilator-free days, length of ICU stay, shorter duration of sedation, and long-term mortality in the early tracheostomy cohort. However, the definition of early tracheostomy did vary in the studies analysed [97].

10. Consider draining large pleural effusions that may be compromising gas exchange and reducing lung compliance, thereby increasing demand on the respiratory muscles.

11. Before extubating weak patients, assess whether they are at increased risk of developing postextubation stridor and whether they are able to protect their airway and clear their respiratory secretions.

When managing patients with discontinuation failure, it is not likely that they fail for technologic reasons or the discontinuation mode but rather because of their diseases and causes of inspiratory muscle fatigue and how well these are managed. Advances for managing discontinuation
from MV, based on randomized, controlled trials or meta-analyses of such trials, are summarized in Table 168.2. A number of studies have been published that show that the most favorable discontinuation outcomes are most likely achieved by protocol-directed weaning. Such programs can improve the quality of care of patients on MV and decrease their length of ICU stay and hospital costs, especially when the protocol includes a search for and correction of medical barriers that perpetuate inspiratory muscle fatigue. In our protocol, we focus on a daily basis on evaluating and managing altered mental status and neuromuscular disease, evaluating and managing cardiac pump failure or coronary ischemia, improving nutrition, treating infection, and reducing lung water without compromising renal function.

**Utility of Ultrasonography for Assessment of Diaphragmatic Function for Discontinuation of Mechanical Ventilation**

The diaphragm is the major inspiratory force generator, so assessment of its function is an important part of the evaluation of the patient with respiratory failure. Diaphragmatic dysfunction may contribute to difficulty of weaning the patient from mechanical ventilatory support as well being a factor in the development of respiratory failure. Ultrasonography is a convenient point-of-care technique for evaluation of diaphragmatic function [98,99].

**Machine Requirements**

For measurement of diaphragmatic excursion (DE), the ultrasonography examination is performed using a phased array cardiac probe (3.5 to 5.0 MHz) whose small footprint allows for examination between rib interspaces. A curvilinear abdominal probe may also be used. For measurement of diaphragmatic thickening (DT) during inspiration, the examination is performed using a linear vascular probe (7.5 MHz).

**Patient Position and Ventilator Setting**

In the ICU, the patient is examined in the supine or semirecumbent position appreciating that the weight of abdominal contents may have effect on DE, particularly if the patient is obese or has an elevation of intrabdominal pressure. The ventilator is set so as to provide minimal or no support during the measurement, because both PEEP and positive pressure ventilation may alter the degree of DE that results from patient effort [100]. The patient may be taken off pressure support or
temporarily disconnected from the ventilator with provision of supplemental oxygen while performing the ultrasonography examination.

**Scanning Technique**

To measure DE on the right side, the phased array transducer is placed over the lower lateral chest wall in the mid-axillary line using a longitudinal scanning axis (coronal plane). Image depth is set deep in order to visualize the entire diaphragm. The hyperechoic curvilinear diaphragm is imaged by adjusting the scanning plane for maximal visualization ([Video 168.1](#)). If aerated lung blocks view of the diaphragm, the probe may be moved caudal and tilted upward to use the liver as a sonographic window to better visualize the diaphragm. Alternatively, using a transverse scanning plane, the probe is placed in the midclavicular line on the right side below the lower rib margin and angled cephalad. The liver serves as a sonographic window to image the curvilinear diaphragm.

To measure DE on the left side, the phased array transducer is placed over the lower lateral chest wall in the mid-axillary line using a longitudinal scanning axis (coronal plane). The hyperechoic curvilinear diaphragm is imaged by adjusting the scanning plane for maximal visualization. The left diaphragm is more difficult to image than the right, so it is often necessary to use the spleen as a sonographic window. The transverse plane mid-clavicular approach is not effective on the left side, because of the presence of bowel gas and absence of the liver forming a sonographic window.

Once the diaphragm is visualized, the examiner observes its movement during quiet breathing, during augmented effort, and with the patient performing a sharp inspiratory effort (“sniff test”) ([Video 168.2](#)). The movement of the diaphragm is straightforward to assess on a qualitative basis: it either moves in a normal caudad direction with inspiration, or it moves in an inappropriate cephalad direction during inspiration ([Video 168.2](#)). Qualitative measurement of diaphragmatic function is made through simple visual assessment. Quantitative measurement of DE is performed with M mode ultrasonography where the interrogation line placed as perpendicular as possible to the major axis of movement of the dome of the diaphragm ([Video 168.2](#)). This may be difficult to achieve from the lateral position, but easier from the mid-clavicular upper quadrant approach on the right side. Some sophisticated cardiology type echocardiography machines have steerable M-mode that facilitates
measurement along the correct axis [101]. Most machines used for point-of-care critical applications do not have this capability. As an alternative, a simple analogue measure with millimeter marks can be applied to the machine screen and adjusted to optimal measurement axis in order to measure the excursion directly.

To measure inspiratory diaphragmatic thickening, the linear vascular transducer is placed in the mid axillary line in longitudinal plane with the depth and gain adjusted in order to visualize the diaphragm. The image is frozen in inspiration and expiration and the thickness measured at the two points using the calipers function (Video 168.2). The degree of thickening is calculated using the following formula:

\[
\text{Diaphragmatic Thickening (\%)} = \frac{\text{Diaphragmatic Thickness}_{\text{inspiratory}} - \text{Diaphragmatic Thickness}_{\text{expiratory}}}{\text{Diaphragmatic Thickness}_{\text{inspiratory}}}
\]

Problems with Measurement

If the patient performs an active expiratory effort with abdominal muscle contraction that results in an end expiratory lung volume that is below FRC, the following inspiratory diaphragmatic movement will be in in caudad direction, but not due solely to diaphragmatic contraction. Rather, it results from inspiratory movement that derives from the elastic recoil of the chest wall. The operator watches for this breathing pattern, because it may mask a nonfunctioning diaphragm.

It may be difficult for the single operator to simultaneously time the inspiratory effort of the patient with diaphragmatic movement on the ultrasonography machine. It is useful to have a continuous tracing of the respiratory cycle running on the ultrasonography machine simultaneous with the ultrasonography image in order to correlate diaphragmatic movement with the respiratory cycle; however, most portable machines used for point-of-care ultrasonography do not have this capability. In this case, one operator is assigned to verbally identify inspiratory effort while the ultrasonographer watches for diaphragmatic movement on the screen, in order to correlate the movement with inspiration.

It may be difficult to make an accurate measurement of excursion unless the measurement axis is the same as the maximal movement axis of the diaphragm. In addition, the degree of excursion will vary according to the point of measurement because the apex of the curved structure moves more than its lateral aspects (Video 168.2).

Measurement of diaphragmatic thickening is in millimeter increments, so detail to correct caliper position is important. The operator averages several measurements and standardizes caliper position often by using an inner edge to inner edge technique (Video 168.2).
Clinical Applications of Ultrasonography Assessment of Diaphragmatic Function

Diaphragmatic dysfunction in patients receiving MV is most often secondary to neuromuscular disorders or non-myopathic diseases such as COPD, to ICU-acquired neuromyopathy, and/or to ventilator-induced diaphragmatic dysfunction, and is therefore symmetric [102–104]. Most studies performed in noncardiac surgery patients report on DE or DT on only one hemidiaphragm (usually on the right side) and use this as a proxy for the total diaphragmatic performance [105–108], although some studies take the lowest value or the mean value between left and right. Four studies describe the use of evaluating diaphragmatic function during weaning in noncardiac surgery patients. Jiang et al. measured the mean value of inspiratory excursions of the liver and the spleen (as a surrogate for DE) during a SBT [109] and demonstrated that patients who required reintubation within 72 hours had significantly lower mean values of liver and spleen displacements than those who did not require reintubation. With a cutoff value of 1.1 cm, the sensitivity and specificity to predict successful extubation were 84% and 83% respectively. Kim et al. reported that a DE value <10 mm for either hemidiaphragm was associated with longer weaning times and higher frequency of reintubation [110]. Both of these studies had unusually high rates of failed extubation thereby limiting their generalizability. Regarding the utility of DT, Di Nino et al. reported that a DT of greater than 30% was associated with positive predictive value of 91% and negative predictive value of 63% for extubation success [108]. Performance of DT was similar, if the measurements were performed during an SBT or a pressure support trial. Ferrari et al. observed in repeated weaning failure that a cutoff value of a DT >36% measured during an SBT on tracheostomy tube was associated with a positive predictive value of 92%, and a negative predictive value of 75% for success or failure from discontinuation of mechanical support at 48 hours [111]. When the performance of ultrasonographic measurements to predict extubation failure or success were compared with clinical parameters such as the rapid shallow breathing index the results were similar. Ultrasonography may be useful to monitor recovery of diaphragmatic recovery over time. Mariani et al. studied DE in patients with prolonged (>7 days) MV and followed DE with repeated measurements in patients with bilateral reduction of DE (E <11 mm) [112]. Some patients had a progressive improvement of DE over time. Grosu et al. observed progressive diaphragmatic thinning in patients receiving volume-controlled MV [113].

On occasion, the intensivist will manage the post-cardiac surgery patient who is difficult to wean from mechanical ventilatory support. Unilateral phrenic nerve injury may lead to asymmetric diaphragmatic
dysfunction following cardiac surgery. Rarely, both hemidiaphragms are paralyzed, thereby precluding weaning from ventilatory support until there is return of function. In cardiac surgery patients, bilateral assessment of DE with identification of the best maximal DE is a useful functional parameter of diaphragmatic performance. Lerolle et al. reported that post-cardiac surgery patients with unilateral diaphragmatic paralysis could be weaned off the ventilator without difficulty, if the contralateral diaphragm had a maximal DE >25 mm [114].

Ultrasonography is useful in order to identify diaphragmatic dysfunction. However, it is an imperfect tool, like other indices that are used to predict the success or failure of extubation. It is possible that its utility will be improved when combined with other predictors, such as the lung aeration score or the rapid shallow breathing index. The causes of weaning failure are often multifactorial, only one of which may be diaphragmatic dysfunction.

Various adjunct therapies are available to aid in the management of critically ill patients with existing or anticipated pulmonary dysfunction. In this chapter, we review several adjunct therapies, emphasizing any randomized trials determining efficacy and indications. We will specifically discuss the following: (a) aerosol therapy and humidification; (b) lung expansion techniques; (c) airway clearance techniques; (d) administration of medical gases; (e) nasal continuous positive airway pressure (CPAP) and bilevel positive airway pressure for sleep-related breathing disorders; and (f) communication alternatives for the patient with an artificial airway. A discussion of the use of bilevel positive airway pressure to provide noninvasive ventilatory support can be found in Chapter 167.

AEROSOL THERAPY

An aerosol is a stable suspension of solid or liquid particles dispersed in air as a fine mist. Bland aerosols are generally used to humidify inspired gases. Aerosol drug therapy represents the optimal modality for site-specific delivery of pharmacologic agents to the lungs in the treatment of a number of acute and chronic pulmonary diseases. Owing to the cost and potential hazards of aerosol therapy, use should be limited to aerosols whose clinical value has been objectively shown [1].

Bland Aerosols

Bland aerosols include sterile water or hypotonic, isotonic, and hypertonic saline delivered with or without oxygen. These are typically delivered via an ultrasonic nebulizer in an effort to decrease or aid in the
clearance of pulmonary secretions. The routine use of bland aerosols in the treatment of some specific diseases has demonstrated mixed results. An evidence-based recommendation for the use of bland aerosols has been released by the British Thoracic Society (BTS) [2]. The use of bland aerosols for the treatment of chronic obstructive pulmonary disease (COPD) and croup appears not to be of any benefit [2,3]. For patients with cystic fibrosis (CF), the use of 7% (hypertonic) saline, administered twice daily, may result in a significantly higher forced vital capacity (FVC) and forced expiratory volume in 1 second (FEV₁), and a decrease in the number of acute exacerbations when compared to the use of normotonic saline [4]. The use of nebulized saline or sterile water may improve sputum clearance for patients with non-CF bronchiectasis [2]. Delivery of bland aerosols to the spontaneous breathing patient is ineffective for liquefying secretions because sufficient volumes of water fail to reach the lower airways. Furthermore, bland aerosols may provoke bronchospasm and place patients at risk for nosocomial pneumonia [3].

Mist therapy, the delivery of a continuous aerosol of sterile water or saline, is frequently used to treat upper-airway infections in children, but has not been shown to be more effective than air humidification [3].

Humidity Therapy

Theoretical reasons for using humidified inspired gas are to prevent drying of the upper and lower airways, hydrate dry mucosal surfaces in patients with inflamed upper airways (vocal cords and above), enhance expectoration of lower-airway secretions, and induce sputum expectoration for diagnostic purposes [3].

Humidity therapy is water vapor and, at times, heat added to inspired gas with the goal of achieving near-normal inspiratory conditions when the gas enters the airway [5]. Because adequate levels of humidity and heat are necessary to ensure proper function of the mucociliary transport system, humidification is imperative when the structures of the upper airway that normally warm and humidify inspired gases have been bypassed by an artificial airway. During mechanical ventilation, humidification is crucial to avoid hypothermia, atelectasis, inspissation of airway secretions, and destruction of airway epithelium because of heat loss, moisture loss, and altered pulmonary function [6]. Optimal humidification is the point at which normal conditions that prevail in the respiratory tract are simulated [7].

Several external devices are available to artificially deliver heat and moisture. Two such devices for mechanically ventilated patients are: (a) a heated waterbath humidifier, which is an external active source of heat and water, and (b) a heat and moisture exchanger filter (HMEF) that passively retains the heat and humidity leaving the trachea during
expiration and recycles it during the next inspiration. HMEFs are also known as *hygroscopic condenser humidifiers* or *artificial noses*. The HMEF is designed to combine air-conditioning and bacterial filtration. In a randomized controlled trial, both devices were shown to be equally safe [8]. Potential advantages of HMEFs over heated waterbath humidifiers include reduced cost and avoidance of airway burns and overhydration. A potential disadvantage is that resistance of airflow through an HMEF may progressively rise, increasing the work of breathing and conceivably impeding weaning from the ventilator [8].

Cold-water devices such as bubble humidifiers are frequently used to add humidity to supplemental oxygen administered to spontaneously breathing patients. Owing to a lack of objective evidence to support the practice, the American College of Chest Physicians recommends elimination of the routine use of humidification of oxygen at flow rates of 1 to 4 L per minute when environmental humidity is sufficient [9], although the BTS does not recommend its use [2].

Patients requiring high-flow rates of oxygen (>10 L per minute) frequently develop discomfort due to upper-airway dryness. There are several devices available to deliver humidification via nasal cannulae at high-flow rates (high-flow oxygen delivery), including Vapotherm (Vapotherm, Annapolis, MD) and the Fisher & Paykel 850 (Fisher and Paykel Healthcare Corp., Auckland, New Zealand). These devices have been shown to improve patients’ comfort [10], and may have some therapeutic benefit (see below).

**Pharmacologically Active Aerosols**

Inhaled therapy has several well-recognized advantages over other drug delivery routes. The drug is delivered directly to its targeted site of action; therefore, when compared to other routes of administration, a therapeutic response usually requires fewer drugs, there are fewer side effects, and the onset of action is generally faster [11]. A broad range of drugs is available as aerosols to treat obstructive lung diseases. These include β-adrenergic agonists, anticholinergics, anti-inflammatory agents, and anti-infectives. Additionally, the inhaled route is used to deliver drugs that are not effective when delivered by the oral route (e.g., pentamidine) [12].

Although a variety of drugs are currently available in aerosolized form, dosing to the lung remains inexact because deposition is affected by several patient-, environment-, and equipment-related factors. Potential
hazards of aerosol drug therapy include (a) a reaction to the drug being administered, (b) the risk of infection, (c) bronchospasm, and (d) the potential for delivering too much or too little of the drug [12]. With respect to the use of aerosolized ribavirin, there are potential hazards to health care providers administering the medication (see later).

**Bronchodilators**

There are two classes of inhaled bronchodilators: (a) $\beta_2$-adrenergic receptor agonists (short-acting, long-acting, and ultra long-acting) and (b) anticholinergic agents.

**Short-Acting $\beta_2$-Adrenergic Receptor Agonists.** Although $\beta_1$- and $\beta_2$-adrenergic receptors are present in the lungs, $\beta_2$-adrenergic receptors appear to be entirely responsible for bronchodilation. Therefore, $\beta_2$-adrenergic receptor agonists (e.g., albuterol, pirbuterol, and terbutaline) are the agents commonly preferred for the relief of acute symptoms of bronchospasm. In addition to the bronchodilating properties of $\beta_2$-adrenergic receptor agonists, other actions include augmentation of mucociliary clearance; enhancement of vascular integrity; metabolic responses; and inhibition of mediator release from mast cells, basophils, and possibly other cells [3]. Inhalation of $\beta_2$-selective agonists is considered first-line therapy for the critically ill asthmatic [13] and COPD patient [3, 14]. Although these agents can be administered orally, by inhalation, or parenterally, the inhaled route is generally preferred because fewer side effects occur for any degree of bronchodilation [3]. For most patients experiencing acute asthma attacks, inhalation is at least as effective as the parenteral route [3]. Inhaled $\beta_2$ agonists can be delivered as an aerosol from a jet or ultrasonic nebulizer or from a metered-dose inhaler (MDI). The relative efficacies of the nebulizer and MDI are dependent on the adequacy of technique. Although it was formerly a standard practice to deliver bronchodilators by nebulizer, several prospective, randomized controlled trials have challenged this practice. Delivering $\beta_2$ agonists by MDI with a spacer device (holding chamber) under the supervision of trained personnel is as effective in the emergency setting as delivery by nebulizer for adults and children [3]. For hospitalized patients, $\beta_2$ agonists delivered by MDI are as effective as therapy with a nebulizer and can result in considerable cost savings [3]. An analysis of 16 trials (686 children and 375 adults) to assess the effects of MDIs with holding chambers compared to nebulizers for the administration of $\beta_2$ agonists
for acute asthma concluded that MDI with a holding chamber produced at least equivalent outcomes as nebulizer delivery [15].

Ideal frequency of administration and dosing of $\beta_2$ agonists has not been determined. For emergency department and hospital-based care of asthma, the National Institutes of Health Expert Panel Report 3 [13] recommends up to three treatments in the first hour, followed by 1 to 4 treatments every 1 to 4 hours as needed. These subsequent treatments should be titrated to the severity of symptoms and the occurrence of adverse side effects, ranging from hourly treatments for moderate severity to hourly or continuous treatments for severe exacerbations. Recommendations for initial treatment of severe acute exacerbations of COPD are for the administration of short-acting $\beta_2$ agonists every 2 to 4 hours if tolerated [3].

When given by jet nebulizer, the usual adult dose of albuterol is 0.5 mL of a 0.5% solution (2.5 mg) diluted in 2.5 mL of saline (or 3 mL of 0.083% unit-dose nebulizer solution). The frequency of dosing varies depending on the disease and the situation. It can range from every 4 to 6 hours for patients with COPD and stable asthma to every 20 to 30 minutes for six doses in patients with status asthmaticus [3]. For patients with acute asthma, albuterol solution has also been continuously nebulized for 2 hours [16]. In this randomized controlled trial of spontaneously breathing patients with FEV$_1$ less than 40% predicted, continuous delivery of high-dose (7.5 mg per hour) or standard-dose (2.5 mg per hour) albuterol were both superior to hourly intermittent treatments with 2.5 mg for increasing FEV$_1$. Although there was no difference in FEV$_1$ improvement between the two continuous doses, the standard dose had fewer side effects.

Although the usual dosage of bronchodilator by MDI is two puffs (90 μg per puff) every 4 to 6 hours in stable hospitalized and ambulatory adult patients, the dosage must be increased up to sixfold in acute severe asthma to achieve results equivalent to those achieved with small-volume nebulizers [3]. In an emergency department treatment study of severe asthma, four puffs of albuterol by MDI every 30 minutes for a total of six dosing intervals (24 puffs) was found to be safe and equivalent to 2.5 mg of albuterol diluted in 2 mL of saline given every 30 minutes for six doses [3]. Others have treated acute episodes of asthma in the emergency department in a dose-to-result fashion as follows: initially four puffs by MDI of bronchodilator of choice, followed by one additional puff every minute until the patient subjectively or objectively improved or side effects (e.g., tremor, tachycardia, and arrhythmia) occurred [3]. For mechanically ventilated patients, the bronchodilator effect obtained with four puffs (0.4 mg) of albuterol from an MDI with holding chamber is comparable to that obtained with 6 to 12 times the same dose given by a
nebulizer and is likely to be more cost-effective [17].

Tremor is the principal side effect of β₂ agonists, due to the direct stimulation of β₂-adrenergic receptors in skeletal muscle. Tachycardia and palpitations are less frequent with the selective β₂ agonists (e.g., albuterol) than with nonselective β₁–β₂ agonists such as isoproterenol. Although vasodilation, reflex tachycardia, and direct stimulation of the heart can occur even with the use of selective β₂ agonists, cardiac adverse occurrences are uncommon when usual doses of inhaled β₂ agonists are administered. A transient decrease of arterial oxygen tension may occur among patients with acute, severe asthma. This response is likely due to the relaxation of the compensatory vasoconstriction in areas of decreased ventilation together with increased blood flow due to increased cardiac output [3].

β₂-Adrenergic agonists can cause acute metabolic responses including hyperglycemia, hypokalemia, and hypomagnesemia [3]. Although typically not seen in standard doses, if large and frequent doses of β agonists are given, electrocardiogram and serum potassium monitoring are indicated. After inhalation of 10- and 20-mg doses, the maximal decreases in potassium can be 0.62 ± 0.09 mmol per L and 0.98 ± 0.14 mmol per L, respectively [18].

Perinatal outcomes of 259 pregnant women with asthma who were treated with β₂-adrenergic agonists during pregnancy were compared to those of 101 women who were not treated with these agents, and 295 nonasthmatic women [3]. There were no differences in perinatal mortality rates, congenital abnormalities, preterm delivery, low birth weights, mean birth weights, or the number of small-for-gestational-age infants. In addition, there were no differences in Apgar scores, labor or delivery complications, or postpartum bleeding.

Levalbuterol (Xopenex, Ñépracor Inc., Marlborough, MA) inhalation solution, the (R)-enantiomer of racemic albuterol, is a relatively selective, third-generation β₂-adrenergic receptor agonist approved for treatment of bronchospasm in adults and children aged 12 years or older. Levalbuterol appears to offer little benefit over albuterol for improving FEV₁ of patients with asthma, and is not associated with any fewer systemic side effects such as tachycardia and hypokalemia [19]. For further discussion of aerosolized β agonists in asthma and COPD, see Chapters 172 and 173.
Long-Acting and Ultra Long-acting Inhaled $\beta_2$ Agonists. Long-acting inhaled $\beta_2$ agonists (e.g., salmeterol and formoterol) and ultra long acting $\beta_2$ agonists (vilanterol and indacaterol) are currently not recommended for use in acute exacerbations of asthma (Expert Panel Report 2) [13] or COPD [3]. One prospective, double-blind, randomized, placebo-controlled trial demonstrated a possible role for salmeterol as an adjunct to conventional therapy for hospitalized asthmatic patients [20], but larger studies are needed to clarify whether there is a potential benefit in the setting of acute asthma. If patients are using these agents as controller medications for asthma or COPD and are hospitalized for other reasons, consider continuing them for asthma maintenance during the hospitalization. These agents should be administered at regular intervals; additional doses to relieve symptoms should not be prescribed.

Anticholinergics. Anticholinergics appear to have a role for acute asthma when combined with sympathomimetic drugs [3], for exacerbations of COPD when combined with albuterol [5], for intubated patients to prevent bradycardia induced by suctioning [21], and in selected patients with severe bronchorrhea [22]. Ipratropium bromide is dosed at 500 μg in 2.5 mL normal saline (1 unit 0.02% unit-dose vial) or 2 to 6 puffs by MDI (18 μg per puff) every 6 to 8 hours. For patients with a severe asthma exacerbation, 500 μg of ipratropium should be given every 20 minutes for three doses [13]. Ipratropium (18 μg per puff) and albuterol (103 μg per puff) are available as a combined MDI product (Combivent, Boehringer, Ingelheim; Ridgefield, CT). Ipratropium by MDI can be given to ventilated patients with the same spacer device used for $\beta_2$-agonist delivery. Tiotropium, a selective muscarinic antagonist, should be limited to the chronic management of patients with COPD. For further discussion of anticholinergic use in asthma and COPD, see Chapters 172 and 173.

Combined Bronchodilator Therapy. Although inhaled short-acting $\beta_2$-adrenergic receptor agonists remain first-line agents in the treatment of acute asthma, the addition of ipratropium bromide may result in an added benefit [23]. Anticholinergics may be of benefit as additive agents or as single agents in situations in which the patient cannot tolerate $\beta_2$-adrenergic side effects. Both agents appear effective in smoking-related chronic bronchitis.

Mucolytics
N-Acetylcysteine. Theoretically, mucolytic agents facilitate expectoration of excessive lower-airway secretions and improve lung function [3]. Although N-acetylcysteine (Mucomyst, Apothecon, Princeton, NJ), the prototypic mucolytic agent, liquefies inspissated mucous plugs when administered by direct intratracheal instillation [24], it is of questionable clinical use when administered as an aerosol to nonintubated patients because very little of the drug is actually delivered to the lower respiratory tract. Inhaled N-acetylcysteine failed to prevent deterioration of lung function or exacerbations of patients with COPD [25], and nebulized N-acetylcysteine failed to demonstrate any benefit for patients with CF [26]. However, a small randomized trial suggested that nebulized N-acetylcysteine in combination with aerosolized heparin reduced the incidence of acute lung injury (ALI) and decreased mortality in patients with acute smoke inhalational injuries [27]. Because mucolytic instillations or aerosols can induce bronchospasm among patients with airway disease [28] (especially asthma), mucolytics should be administered to these patients in combination with a bronchodilator [3]. However, given the lack of evidence from randomized trials supporting its benefits, we do not recommend the routine use of aerosolized N-acetylcysteine.

Recombinant Human DNase. Recombinant human DNase (Pulmozyme, Genentech, South San Francisco, CA), when given as an aerosol in a dose of 2.5 mg once or twice a day to patients with CF, led to a moderate but significant decrease in dyspnea, a reduction of costs related to exacerbations of respiratory symptoms, and a modest improvement in FEV₁ after 3 months [2]. However, there may not be any statistically significant therapeutic benefit of rhDNase when added to antibiotics and chest physical therapy [29]. Two double-blind, placebo-controlled clinical trials evaluated the safety and efficacy of nebulized rhDNase in the treatment of non-CF–related bronchiectasis [30,31]. In these studies, rhDNase was consistently found ineffective (and possibly harmful [30]) to patients with non-CF–related bronchiectasis.

A randomized double-blind, placebo-controlled trial of patients with respiratory syncytial virus (RSV) bronchiolitis found significant improvement of chest radiographic findings that occurred with the use of nebulized rhDNase compared to significant worsening of those from a placebo group. Although further investigation is needed, results of this trial indicate a possible future role for this therapy in the treatment of RSV in infants and young children [32].

Other Mucolytics. Studies to determine the efficacy of other mucolytic agents, including water, have produced conflicting results. Current

**Anti-Infectives**

Aerosolization of antimicrobial solutions has been shown to be effective in CF patients with tracheobronchial infections and colonization [2]. In addition, inhaled antibiotics have also been used to treat tracheobronchial infections for patients with non-CF–related bronchiectasis, to treat and prevent ventilator-associated pneumonia, to treat chronic bronchitis for patients with COPD, to treat bronchiolitis of children, and to treat patients with multidrug-resistant tuberculosis (MDR-Tb) and mycobacterium avium complex (MAC) [11]. However, unlike their use in treating patients with CF, the benefits of using inhaled antibiotics for these other indications is less defined. Inhaled tobramycin has been demonstrated to decrease sputum bacterial counts, improve lung function, decrease the number of exacerbations, and improve quality of life for patients with pulmonary infections or colonization from CF [33]. For patients with non-CF–related bronchiectasis, inhaled antibiotics are not as well studied, but may decrease sputum bacterial counts and decrease the number of hospitalizations, but have no impact on lung function or survival [34]. Inhaled antibiotics have not been shown to provide any benefits for patients with chronic bronchitis or COPD [35]. Prophylactic use of inhaled antibiotics to decrease the risk of developing ventilator-associated pneumonia has not been shown to be of any benefit [35]. In addition, inhaled antibiotics appear to have no benefit over systemic antibiotics for treating ventilator-associated pneumonia [35]. A few small studies suggest that inhaled amikacin and rifampicin may be of some benefit for treating severe MDR-Tb and severe infections with MAC [36].

Currently only tobramycin, colistin, and aztreonam are FDA approved for inhalational use. Other antibiotics occasionally administered via an aerosol include amikacin, gentamicin, levofoxacin, azithromycin, vancomycin, ceftazidime, and imipenem. Inhaled colistin should be used with great caution as it decomposes into several toxic compounds that, if inhaled, can result in ALI and respiratory failure. Colistin suspension should be administered within 6 hours after it is prepared [37].

Inhaled tobramycin is approved for treatment of patients with CF who
are (a) at least 6 years of age, (b) have FEV\textsubscript{1} greater than or equal to 25% and less than or equal to 75% predicted, (c) are colonized with \textit{Pseudomonas aeruginosa}, and (d) are able to comply with the prescribed medical regimen [33]. When nebulizing tobramycin, it has been shown that different nebulizers and solutions and techniques may result in very different amounts of tobramycin being inhaled [38]. For example, the addition of albuterol lowered the surface tension of the solution in the nebulizer and resulted in a greater output of tobramycin. A prospective study [39] determined that antibiotics aerosolized by nebulizer could be effectively delivered to tracheostomized, mechanically ventilated patients. In this study, antibiotic concentrations similar to or greater than those achieved among spontaneously breathing individuals were “consistently demonstrated” in patients with a tracheostomy tube.

Aerosolized ribavirin has been used for patients with RSV infection and severe lower respiratory tract disease, or infants with chronic underlying conditions such as cardiac disease, pulmonary disease, or a history of prematurity [3]. However, proof of effectiveness in treating RSV infections is lacking. One study failed to establish the efficacy of inhaled ribavirin for immunocompromised adults with RSV infections [40]. Two prospective double-blind, randomized, placebo-controlled trials addressing the use of aerosolized ribavirin in treating children and adults with respiratory failure from RSV infections failed to show any improvement in the length of time requiring mechanical ventilation, length of stay in the intensive care unit, and oxygen requirements or alter immediate outcome [3]. Aerosolized ribavirin has been suggested to be beneficial for treating infections due to influenza A and B [41]. However, a randomized double-blind, placebo-controlled trial found that aerosolized ribavirin only resulted in accelerating normalization of temperature of children with influenza, but had no effect on respiratory rate, pulse rate, cough, or level of consciousness [42].

Ribavirin, in combination with systemic corticosteroids, was used empirically for the treatment of severe acute respiratory syndrome (SARS). However, a review of 14 clinical reports failed to demonstrate that ribavirin decreased the need for mechanical ventilation, or mortality, of patients with SARS [43].

There are several potential hazardous effects of aerosolized ribavirin. It can cause nausea, headaches, and bronchospasm [44]. In addition, it poses potential risks to health care workers who administer the medication. It has been shown to cause conjunctivitis as it can precipitate on contact lenses, and bronchospasm in health care workers administering the medication [44]. In addition, ribavirin is highly teratogenic. Although studies suggest that absorption of ribavirin by health care workers administering the medication is minimal [3], the short-term and long-term risks to women remain unknown. Therefore,
Conservative safety practices must be followed [3,44]. Given the lack of evidence supporting its efficacy, its known and potential side effects, and the availability of more efficacious treatment options, we do not recommend the use of aerosolized ribavirin for treating infections with RSV. Further studies are needed to determine its efficacy for treating influenza.

Although studies of patients with acquired immunodeficiency syndrome suggest that aerosolized pentamidine can be effective and well tolerated in mild Pneumocystis jiroveci pneumonia, it is not recommended for routine clinical practice [45]. Although aerosolized pentamidine has been used with success for primary and secondary P. jiroveci pneumonia prophylaxis [45], trimethoprim–sulfamethoxazole has been recommended as the drug of choice for prophylaxis in both situations. Aerosolized pentamidine (300 mg reconstituted with sterile water, administered every 4 weeks), delivered by a Respigrad II nebulizer (Marquest, Englewood, CO), has been approved for P. jiroveci pneumonia prophylaxis [45]. A retrospective study suggested that a standard ultrasonic nebulizer (Fisoneb, Fisons, NY) would yield similar effects to Respigrad II, a jet nebulizer, in providing primary and secondary prophylaxis with aerosolized pentamidine [46]. Because toxicity studies on the secondhand effects of aerosolized pentamidine exposure on health care personnel are limited [47], conservative safety practices are necessary.

Corticosteroids

At present, there is no indication for the use of inhaled corticosteroids for the treatment of the critically ill with acute exacerbations of obstructive lung disease. Systemic corticosteroids (oral or intravenous) are the recommended first-line agents for the treatment of acute asthma [13] and COPD [3]. Because inhaled corticosteroids are an integral component of asthma therapy, on discharge, they should be used for all patients receiving tapering doses of oral prednisone. They are considered the most effective anti-inflammatory therapy for control of persistent asthma [13]. Inhaled corticosteroids are available as MDIs, dry-powder inhalers, or inhalation suspension (budesonide) for aerosolized use.

When patients are hospitalized for reasons other than acute airway obstruction, inhaled corticosteroids may be continued if patients have been taking these agents for asthma or COPD maintenance therapy. To reduce the risk of oral candidiasis, mouth rinsing and use of a spacer device with MDI are recommended.

Racemic Epinephrine
Racemic epinephrine is effective for decreasing laryngeal edema by causing vasoconstriction [3]. The usual adult dose is 0.5 mL of a 2.25% solution diluted in 3 mL of normal saline every 4 to 6 hours. Because rebound edema frequently occurs, patients must be observed closely. Tachycardia is common during treatment and may precipitate angina among patients with coronary artery disease [3]. The role of racemic epinephrine aerosol for epiglottitis is not known. Similarly, inhaled racemic epinephrine is used to treat postextubation stridor, but this use has not been rigorously studied. Nebulized racemic epinephrine appears to have no benefit over nebulized albuterol for the management of bronchiolitis [48]. Because racemic epinephrine aerosol is associated with potentially serious side effects among patients with coronary artery disease, administration of inhaled mixtures of helium and oxygen should be considered first to decrease airway resistance and, therefore, the work of breathing associated with laryngeal edema or other upper-airway diseases (see ‘Helium-Oxygen [Heliox]’ section).

**Aerosolized Vasodilators.** Iloprost is an approved inhaled prostacyclin analog used for the chronic treatment of primary pulmonary hypertension and pulmonary hypertension due to use of appetite suppressants, portopulmonary syndrome, connective tissue disease, and chronic thromboembolic disease. It has also been used in patients with acute pulmonary hypertension after coronary bypass surgery, and may be more effective than inhaled nitric oxide (NO) [49]. It is currently FDA approved for patients with primary pulmonary hypertension and New York Heart Association (NYHA) class III (symptoms with minimal activity) and class IV (symptoms at rest) symptoms. Iloprost is administered as 2.5 to 5 μg doses, 6 to 9 times per day. It needs to be delivered via a specialized nebulizer system, the Prodose AAD system (Respironics, Murrysville, PA), to ensure proper dosing. A randomized double-blind, placebo-controlled trial demonstrated that iloprost produced improvements in 6-minute walk, hemodynamics, dyspnea, and quality of life after 12 weeks of therapy [50].

Inhaled prostacyclin has also been used to treat patients with severe acute respiratory distress syndrome (ARDS). Although aerosolized prostacyclin has been shown to improve oxygenation and reduce pulmonary arterial pressures, it does not improve overall outcomes and may be associated with adverse events including systemic hypotension [51]. Its routine use is not recommended, and it is typically reserved for patients with life-threatening hypoxemia refractory to other interventions.
Inhaled Cyclosporin. A randomized double-blind, placebo-controlled trial demonstrated improvement of survival and longer periods free of chronic rejection among lung transplant patients treated with inhaled cyclosporin [52]. The patients in the treatment group received 300 mg of aerosolized cyclosporin (Novartis, East Hanover, NJ) three times a week for the first 2 years after lung transplantation, in addition to usual systemic immunosuppression. There was no increased risk of side effects or opportunistic infections among the treated group.

Modes of Delivery

In the critical care setting, there are generally two types of aerosol delivery devices in use: those that create and deliver wet particles (air-jet nebulizers) and those that deliver preformed particles (pressurized MDIs) with or without MDI auxiliary delivery systems (spacers). Patients on mechanical ventilation or patients breathing through a tracheostomy cannot use dry-powder inhalers. Successful aerosol therapy is dependent on the percentage of the drug that is delivered to the lungs. Factors that influence aerosol deposition and effectiveness, such as flow rate, breathing pattern, and incoordination, have been largely overcome with newer and more advanced designs.

Nebulizers

Air-jet nebulizers are a nonpropellant-based option for inhaled drug delivery. Jet nebulizers rely on a high gas flow (provided by a portable compressor, compressed gas cylinder, or 50-psi wall outlet), Venturi orifices, and baffles to generate respirable particles, generally in the range of 1 to 5 μm in diameter [3]. Small-volume nebulizers, equipped with small fluid reservoirs, are used for drug delivery [3]. Factors that affect their performance include design, characteristics of the medication, and gas source. Large-volume nebulizers have reservoir volumes greater than 100 mL and can be used to deliver aerosolized solutions over an extended period. Large versions are used to deliver bland aerosols into mist tents.

Nebulizers are frequently used for pediatric and elderly populations as well as in the hospital setting. Nebulizer delivery of aerosolized drugs is indicated when a drug is not available in MDI form and when a patient cannot coordinate the use of an MDI. Disadvantages include the need for a gas flow source, lack of portability, cost, and the risk of bacterial contamination if not properly cleaned [53].

Metered-Dose Inhalers
An MDI is a pressurized canister that contains drug suspended in a propellant and combined with a dispersing agent. The canister is inverted, placed in a plastic actuator, and, when pressed, delivers a metered dose of drug. The MDI is capable of delivering a more concentrated drug aerosol, as a bolus, than the solutions commonly available for nebulizers [3]. Delivery of a therapeutic dose is dependent on the quality of the patient’s technique that requires a slow, deep inhalation followed by a breath hold (approximately 10 seconds). Because this maneuver can be difficult, especially if the patient is experiencing respiratory distress, it is essential that the technique be taught and supervised by trained personnel.

Older MDIs use chlorofluorocarbon propellants (CFCs). Their use has now been phased out after the United Nations passed the 1987 Montreal Protocol that called for the banning of substances that may adversely affect the ozone layer. Although medical devices were initially exempted, many pharmaceutical companies began to formulate alternative preparations and delivery systems. Hydrofluoroalkane-134a (HFA) has been found to be an effective alternative to CFCs. In addition, dry-powder inhalers for long- and short-acting β₂ agonists, corticosteroids, and tiotropium have been developed. Another advantage of the HFA-containing MDIs and the dry-powder inhalers is that lung deposition of the medication appears to be greater when compared to the CFC-containing MDIs.

**Metered-Dose Inhaler Auxiliary Devices.** To overcome problems such as incorrect administration, oropharyngeal deposition, and inconsistent dosing associated with MDI aerosol delivery, several auxiliary devices (i.e., spacer, holding chamber) were developed [3]. When used properly, these devices have the following advantages: (a) a smaller, more therapeutic particle size is achieved; (b) oropharyngeal impaction is decreased; (c) fewer systemic side effects are experienced due to less oropharyngeal deposition compared to MDI alone; and (d) the risk of oral thrush associated with inhaled corticosteroids is decreased. It has been shown that among patients who have difficulty with coordination—particularly the elderly, handicapped, infants, and children younger than 5 years of age—spacer devices improve the efficacy of MDIs [54].

**Choice of Delivery System**

Since the development of the first MDI in the 1960s, there has been continuing debate about which aerosol delivery system, nebulizers, or MDI is superior. In 1997, Turner et al. [55] published a meta-analysis of 12 studies that compared bronchodilator delivery via nebulizer to delivery
via MDI. Studies included in the review were all randomized clinical trials of adults with acute asthma or COPD who were treated in the emergency department or hospital and measured FEV$_1$ or peak expiratory flow rate. In all but two of the trials, spacers were used with MDIs. Based on the results of these studies, the authors concluded that there was no difference in effectiveness between the two delivery methods.

A Cochrane Library meta-analysis by Cates et al. [15] compared the clinical outcomes of adults and children with acute asthma who received $\beta_2$ agonists by nebulizer or MDI with spacer. In this review that included 16 randomized controlled trials, the authors concluded that the outcomes (hospital admission, length of stay in the emergency department, respiratory rate, heart rate, arterial blood gases, tremor and lung function) of both groups were equivalent.

In the United States, MDIs are underused in the acute care setting [3]. Barriers to selection of these devices include reimbursement issues and the misconception of clinicians regarding efficacy. Many third-party payors reimburse for the nebulizer/drug package but not for the MDI. In the critical care setting, selection of an aerosol delivery system for the spontaneously breathing patients should be based on several factors. In general, because the MDI with or without spacer is the most convenient and cost-effective method of delivery, it should be chosen whenever possible. Its use may be limited by factors such as the patient’s ability to actuate and coordinate the device, either of which can affect aerosol deposition to the lungs; patient preference; practice situations; and economic evaluations. Additionally, parenchymal dosing with drugs such as pentamidine and ribavirin requires the use of a nebulizer [3]. Cost considerations may determine which delivery system is chosen in different settings. Studies show that use of MDIs with spacers likely produce considerable reductions in hospital costs [56]. The cost of a disposable nebulizer system in a hospital setting may be lower than the cost of a MDI and spacer device if patients are discharged with a second spacer device [15].

Aerosols can be delivered to intubated and mechanically ventilated patients with small-volume side-stream nebulizers connected to the inspiratory tubing or MDIs with an aerosol holding chamber. Although both delivery systems are effective for delivering aerosolized medications to the ventilated patient [3], drug delivery can be significantly reduced if proper technique in setting up and using both devices is not followed.
A lung-expansion technique is any technique that increases lung volume or assists the patient with increasing lung volume above that reached at his or her usual unassisted or uncoached inspiration. Rationales for the use of various strategies to promote lung inflation include (a) increasing pulmonary compliance, (b) increasing partial arterial pressure of oxygen (PaO$_2$), (c) decreasing work of breathing, and (d) increasing removal of secretions [57]. Lung-expansion techniques are meant to duplicate a normal sigh maneuver. Theoretically, sighs or periodic hyperinflations to near-total lung capacity reverse microatelectasis [3].

Lung-expansion techniques are indicated to prevent atelectasis and pneumonia among patients who cannot or will not take periodic hyperinflations [3], such as postoperative upper-abdominal and thoracic surgical patients and patients with respiratory disorders due to neuromuscular and chest wall diseases. Adequately performed, maximum inspirations 10 times each hour while awake significantly decrease the incidence of pulmonary complications after laparotomy [58]. Whatever technique is used postoperatively (e.g., coached sustained maximal inspiration with cough, incentive spirometry, volume-oriented intermittent positive-pressure breathing, intermittent CPAP, or positive expiratory pressure [PEP] mask therapy [59]), it should be taught and practiced preoperatively. When properly used, coached sustained maximal inspiration with cough and incentive spirometry—the least expensive and safest techniques—are as effective as any other method [60]. Of the several commercially available incentive spirometers, the one chosen should combine accuracy, low price, and maximum patient accessibility [61]. Because there are no definitive studies comparing the relative efficacy of volume- and flow-oriented incentive spirometers, the choice of equipment must be based on empiric assessment of patient acceptance, ease of use, and cost. When chest percussion with postural drainage is added to the previously mentioned expansion techniques for patients without prior lung disease, it has failed to affect the incidence of postoperative pulmonary complications [62].
Efficient mucociliary clearance and effective cough are the two basic processes necessary for normal clearance of the airways. In abnormal situations, this system may be dysfunctional and lead to mucus retention. Both the ACCP [63] and the BTS [2] have published evidence-based guidelines reviewing both pharmacologic and nonpharmacologic methods of augmenting pulmonary secretion clearance. Both guidelines are complete reviews on this topic. A summarized discussion of techniques aimed at enhancing airway clearance follows.

Augmentation of Mucociliary Clearance

Mucociliary clearance is one of the most important defense mechanisms of the respiratory system. Mucociliary dysfunction is any defect in the ciliary and secretory elements of mucociliary interaction that disturbs the normal defenses of the airway epithelium [64]. Ineffective mucociliary clearance leads to retention of tracheobronchial secretions. Mucociliary clearance may be ineffective because of depression of the clearance mechanisms or oversecretion in the face of normal mucous transport, or both. Mucus is ineffectively cleared and overproduced by smokers with or without chronic bronchitis and by asthmatic patients [3]. It is also ineffectively cleared in the following situations: (a) among patients with emphysema, bronchiectasis, and CF; (b) during and up to 4 to 6 weeks after viral upper respiratory tract infections; (c) during and for an unknown period after general anesthesia due to the inhalation of dry gas and cuffed endotracheal tubes used during surgery; and (d) during prolonged endotracheal intubation due to the presence of the cuffed tube, administration of elevated concentrations of inspired oxygen, and damage to the tracheobronchial tree from suctioning [3]. The most important consideration for improving mucociliary clearance is to remove the inciting cause(s) of ineffective clearance and overproduction of secretions.

Treatment

Mucociliary clearance can be enhanced pharmacologically and mechanically. Numerous drugs with potential mucociliary effect have been studied, but only a few are clinically useful. Pharmaceutical therapy is frequently used in conjunction with physical therapy.

Pharmacologic Augmentation. β agonists and aminophylline
stimulate mucociliary clearance \[^3\]. These drugs should be given in the same doses given for bronchodilatation. Mucolytics and expectorants (e.g., potassium iodide, glyceryl guaiacolate, guaifenesin, ammonium chloride, creosote, and cocillana) have not been shown to increase mucociliary clearance \[^3\]. There is no evidence to support the use of mucokinetic agents for COPD exacerbations \[^3\]. In a randomized controlled trial, healthy volunteers and patients with mild asthma showed no improvement of mucociliary clearance when given inhaled furosemide \[^65\].

In vitro studies have demonstrated that corticosteroids reduce mucus secretion from human airway cells \[^66\], and the use of inhaled corticosteroids has been recommended for the management of bronchorrhea (i.e., mucus secretions of more than 100 mL per day) \[^67\]. However, we know of no randomized controlled trials demonstrating the benefit of inhaled corticosteroids in the management of bronchorrhea.

**Mechanical Augmentation**

**Chest physiotherapy (CPT).** Usually, CPT involves (a) gravity (therapeutic positioning), (b) percussion to the chest wall over the affected area, (c) vibration of the chest wall during expiration, and (d) coughing. Coughing appears to be the most important component of CPT (see ‘Augmentation of Cough Effectiveness’ section). It is felt to be beneficial for patients with CF and bronchiectasis, in the unusual COPD patient who expectorates more than 30 mL of sputum each day \[^63\], and for patients with lobar atelectasis \[^2\]. It is not indicated for asthmatic patients \[^63\] or for those with uncomplicated pneumonias \[^2\]. CPT does not improve FEV\(_1\), provides only modest short-term effects, and long-term benefits are unproven \[^63\]. For patients with COPD, alternative methods of airway clearance (see below) have not proven more effective than CPT, and the effects of CPT itself on patients with COPD may be minimal \[^68\].

Complications of CPT are infrequent yet potentially severe \[^69\]. They include massive pulmonary hemorrhage (perhaps caused by clots dislodged during percussion), decreased PaO\(_2\) from positioning the “good” lung up in spontaneously breathing patients, rib fractures, increased intracranial pressure, decreased cardiac output, and decreased FEV\(_1\).

**Oscillatory devices.** These devices include the flutter device (Varioraw SARL, Scandipharm Inc, Birmingham, AL), intrapulmonary percussive ventilation (Percussionator, IPV-1; Percussionaire, Sand Point, ID), and high-frequency chest wall oscillation. The flutter mucus clearance device is a small, handheld, pipe-like device used to facilitate the removal of mucus from the lungs. As patients exhale through the
device, a steel ball rolls and bounces, producing vibrations that are transmitted throughout the airways. It is postulated that vibrations of the airways intermittently increase endobronchial pressure and accelerate expiratory airflow, thereby enhancing mucus clearance [70]. In a randomized controlled trial, the flutter device was compared to standard, manual chest therapy in hospitalized CF patients experiencing an acute exacerbation [71] and found to be a safe, efficacious, and cost-effective alternative to standard, manual chest percussion. Konstan et al. [70] compared periods of vigorous voluntary cough, postural drainage, and flutter-valve treatment. Among the therapies compared, the volume of sputum was three times greater with the flutter treatment. Although larger clinical trials are needed, it appears to be a useful device for self-administration of CPT and as an equal alternative to CPT [63].

Intrapulmonary percussive ventilation uses short bursts of air at 200 to 300 cycles per minute, along with entrained aerosols delivered via a mouthpiece [63]. In a study on patients with CF, this was found to be equal to CPT [72]. A small study suggested that high-frequency chest wall oscillation decreased breathlessness and fatigue in patients with ALS [73]. High-frequency chest wall oscillation delivered through an inflatable vest appears to offer no benefit over standard CPT [3].

**PEP mask.** In PEP therapy, a mask is applied tightly over the mouth and nose, and a variable-flow resistor is adjusted to achieve PEP during exhalation between 5 and 20 cm H₂O. This, combined with “huff” coughing, allows mobilization of peripherally located secretions upward into larger airways. A Cochrane review of 20 studies in patients with CF failed to demonstrate that PEP had any short-term benefits over CPT [74].

**Mechanical insufflation–exsufflation.** Mechanical insufflation–exsufflation (cough in-exsufflator) increases the volume inhaled during the inspiratory phase of cough, thereby increasing cough effectiveness [63]. Cough efficiency can be further enhanced by applying negative airway pressure for 1 to 3 seconds after the initial inspiration. This method appears to be most beneficial for patients with impaired cough due to neuromuscular disease [75].

In summary, the data available, although not abundant, indicate that in patients with copious secretions, clearance of secretions can be enhanced with selected physical therapy procedures. Although these modalities appear to increase expectoration of mucus, it is not clear what clinical
benefit this achieves. There is no information about the influence of physical therapy maneuvers on health care outcomes, including frequency of hospitalization, hospital length of stay, longevity, and quality of life. It is clear that these techniques are well entrenched in the management of patients with mucus hypersecretion, especially those with CF; it is time for us to prove that they lead to clinically important outcomes. Evidence-based guidelines for the use of these modalities can be found elsewhere [2,63].

**Suctioning.** Although mechanical aspiration or suctioning is routine in most hospitals, many are unaware of the numerous potential complications associated with suctioning, such as tissue trauma, laryngospasm, bronchospasm, hypoxemia, cardiac arrhythmias, respiratory arrest, cardiac arrest, atelectasis, pneumonia, misdirection of catheter, and death [3]. Complications are generally avoidable or reversible if proper technique and indications are adhered to strictly.

**Endotracheal.** Endotracheal suctioning is performed for patients with an artificial tracheal airway in place. It should be used only when there is definite evidence of excessive retained secretions. Routine suctioning according to a predetermined schedule may cause excessive mucosal tissue damage, excessive impairment of mucociliary clearance, unnecessary exposure to the potential risks of hypoxemia associated with the procedure, arrhythmias, atelectasis, and bronchoconstriction [3]. Endotracheal suctioning is indicated when there is a need to (a) remove accumulated secretions, (b) obtain a sputum specimen for microbiologic or cytologic examination, (c) maintain the patency and integrity of the artificial airway, and (d) stimulate cough in patients with ineffective cough [76].

Suction catheters are generally 22 inches long (adequate in length to reach the main stem bronchus) and sized in French units. Most have a side port to minimize mucosal damage. To avoid obstruction of the artificial airway, the outer diameter of the suction catheter should be less than half the size of the internal diameter of the endotracheal tube (rule of thumb: multiply the inner diameter of the endotracheal tube by 2 and use next smallest size [e.g., 8.0-mm endotracheal tube: $2 \times 8 = 16$, choose next smallest size = 14 French]) [77].

For patients receiving ventilatory support, closed, multiuse systems that are incorporated into the ventilator circuit are available. Because patients remain connected to the ventilator during suctioning, positive end-expiratory pressure (PEEP) and high fractional inspiration of oxygen ($\text{FiO}_2$) can be maintained, reducing the risk of hypoxemia. Preoxygenation with 100% $\text{O}_2$ is still necessary. The use of closed, multiuse systems may reduce costs and the risk of cross-contamination.
However, these systems may increase tension on the tracheal tube and add resistance to the airway. The practice of instilling normal saline into the airway before suctioning to aid secretion removal is common, but it is unclear whether it is effective and it may increase the risk of nosocomial pneumonia. The routine use of saline irrigation is not recommended [77].

**Nasotracheal.** Although nasotracheal suctioning may be considered for patients who do not have an artificial tracheal airway, it is not recommended because of the potential side effects, and there are other, safer alternatives. It is rarely indicated because CPT can be used in conscious patients, and semicomatose or comatose patients with retained secretions can be intubated. Nasotracheal suctioning has been associated with fatal cardiac arrest, life-threatening arrhythmias presumably due to hypoxemia, and bacteremia [3]. Because quantitative cultures acquired with plugged telescoping catheters at bronchoscopy can be obtained more safely and are definitely more reliable than nasotracheal suction (see Chapter 10) in obtaining uncontaminated lower respiratory tract secretions for culture, nasotracheal suction is not recommended for this purpose.

**Nasopharyngeal.** Nasopharyngeal suctioning is indicated to clear the upper airway. Because the catheter does not reach the vocal cords or enter the trachea, nasopharyngeal suctioning is associated with fewer complications than nasotracheal suctioning [3]. The catheter should not touch or go beyond the vocal cords. This requires insertion to a depth that corresponds to the distance between the middle of the patient’s chin and the angle of the jaw, just below the earlobe.

**Endotracheal extubation.** Before removal of the endotracheal tube, perform nasopharyngeal and oropharyngeal suctioning to clear secretions that have pooled above the vocal cords for the inflated cuff. Replace the catheter and perform endotracheal suctioning. In preparation for deflating the cuff, place the endotracheal suction catheter tip just distal to the endotracheal tube to aspirate any secretions that gravitate downward when the cuff is deflated. Deflate the cuff and intermittently suction while removing the tube and catheter as a unit.

**Augmentation of Cough Effectiveness**

Although mucociliary transport is the major method of clearing the airway in healthy subjects, cough is an important reserve mechanism, especially in lung disease [3]. All studies suggest that cough is effective in clearing secretions only if secretions are excessive.
Pathophysiology of Ineffective Cough

The effectiveness of cough for clearing an airway theoretically depends on the presence of secretions of sufficient thickness to be affected by two-phase, gas–liquid flow and the linear velocity of air moving through its lumen [3]. The ineffectiveness of voluntary coughing in normal subjects to clear tagged aerosol particles in the lower airways is probably due to the inability of the moving airstream to interact appropriately with the normally thin mucus layer on which the particles were deposited [3]. Once there is sufficiently thick material in the airways, the effectiveness of cough depends on achieving a high expiratory flow rate of air and a small cross-sectional area of the airway during the expiratory phase of cough to achieve a high linear velocity (velocity equals flow/cross-sectional area); therefore, any condition associated with decreased expiratory flow rates or reduced ability to compress airways dynamically places affected patients at risk of having an ineffective cough.

All conditions that may lead to an ineffective cough interfere with the inspiratory or expiratory phases of cough; most conditions affect both. Cough effectiveness is likely to be most impaired in patients with respiratory muscle weakness because their ability to take in a deep breath (flow rates are highest at high lung volumes) and to compress their airways dynamically during expiration are impaired, placing them at double liability. The muscles of expiration appear to be the most important determinant for producing elevated intrathoracic pressures, and they are capable of doing so even with an endotracheal tube in place [3]. Therefore, tracheostomy should not be performed in the intubated patient just to increase cough effectiveness.

Assessment of Cough Effectiveness

Ideally, clinicians would like to predict clinically or physiologically when a patient is at risk of developing atelectasis, pneumonia, or gas-exchange abnormalities because of an ineffective cough. There are no such studies, however. The existing data that relate to assessment of cough effectiveness were generated in patients with muscular dystrophy and myasthenia gravis [3,78]. These studies suggested that mouth maximum expiratory pressure (MEP) measurements may be useful for assessing cough strength, but they did not correlate these measurements with any clinical outcomes. Using the absence of peak flow transients (i.e., a spike of flow with a cough to the otherwise sustained maximal expiratory flow) during cough flow–volume curves as an indication that expiratory muscle
strength during coughing was not adequate to compress the airways dynamically, investigators found that MEP was the most sensitive predictor of flow transient production during coughing [3]. All patients who could produce cough transients had MEP values greater than 60 cm H₂O; those who could not produce transients had MEP values of 45 cm H₂O or less. This latter value is consistent with the clinical observations of Gracey et al. [78], who found in patients with myasthenia gravis that MEP values less than 40 cm H₂O were frequently associated with difficulty in raising secretions without suctioning.

Bach and Saporito [79] prospectively evaluated measurement of peak cough flows (PCF) (assisted and unassisted) as a predictor of successful extubation and decannulation among 49 patients with primary neuromuscular ventilatory insufficiency. In this study, the ability to generate at least 160 L per minute of PCF (measured with Peak Flow Meter, HealthScan Inc, Cedar Grove, NJ) resulted in successful extubation or decannulation, whereas no patients with PCFs under 160 L per minute were successfully extubated or decannulated. The authors concluded that the assisted PCF could be used to predict the ability to safely extubate or decannulate patients with neuromuscular disease regardless of the extent of ventilatory insufficiency.

Protussive Therapy

When cough is useful yet inadequate, protussive therapy is indicated (e.g., bronchiectasis, CF, pneumonia, postoperative atelectasis) [3]. The goal of protussive therapy is to increase cough effectiveness with or without increasing cough frequency. It can be of a pharmaceutical or mechanical nature.

Only a small number of pharmacologic agents have been adequately evaluated as protussive agents [80]. Of these, aerosolized hypertonic saline in patients with chronic bronchitis and amiloride aerosol in patients with CF have been shown to improve cough clearance [3,81]. Although aerosolized ipratropium bromide diminished the effectiveness of cough for clearing radiolabeled particles from the airways in COPD, aerosolized terbutaline after CPT significantly increased cough clearance in patients with bronchiectasis [3]. The conflicting results with these two types of bronchodilators suggest that terbutaline achieved its favorable effect by increasing hydration of mucus or enhancing ciliary beating, and these overcame any negative effects that bronchodilation had on cough clearance. If bronchodilators result in too much smooth muscle relaxation of large airways, flow rates can actually decrease even in healthy individuals when more compliant large airways narrow too much because they cannot withstand dynamic compression during forced
Although hypertonic saline, amiloride, and terbutaline by aerosol after CPT have been shown to increase cough clearance, their clinical use remains to be determined in future studies that assess short-term and long-term effects of these agents on the patient's condition.

**Expiratory Muscle Training**

Because expiratory muscle weakness diminishes cough, strengthening the muscles may improve cough effectiveness. In quadriplegic subjects, there was a 46% increase in expiratory reserve volume after a 6-week period of isometric training to increase the clavicular portion of the pectoralis major [82]. This technique may improve cough by allowing patients with neuromuscular weakness to generate higher intrathoracic pressures [3].

**Mechanical Measures**

A variety of mechanical measures have been advocated as possible therapies to improve cough effectiveness [3], including (a) positive mechanical insufflation, followed by (b) manual compression of the lower thorax and abdomen in quadriparetic patients (an abdominal push maneuver that assists expiratory efforts in patients with spinal cord injuries), (c) mechanical insufflation–exsufflation, (d) abdominal binding and muscle training of the clavicular portion of the pectoralis major in tetraplegic patients, and (e) CPT in patients with chronic bronchitis. The usefulness of the first four measures for improving clinical outcomes has yet to be studied; and, among patients with CF, one technique does not appear to be superior to the others [3]. For patients with chronic bronchitis, the combination of short bouts of PEP breathing, forced expirations, and CPT resulted in reduced coughing, less mucus production, and fewer acute exacerbations compared with patients who received CPT alone. Except for patients with CF, there is no clear benefit of combining CPT with coughing over vigorous coughing alone [63].

The effects of deep lung insufflation on maximum insufflation capacities and PCF for patients with neuromuscular disease were investigated [83]. In this study, the authors concluded that with training, the capacity to stack air to deep insufflations can be enhanced despite neuromuscular weakness, and this can result in increased cough effectiveness.
ADMINISTRATION OF MEDICAL GASES

Oxygen Therapy

Indications for Oxygen Therapy

In the acute setting, administration of supplemental oxygen is indicated for (a) acute respiratory failure (hypoxemic and hypercapnic), (b) acute myocardial infarction (MI), (c) acute asthma, (d) normoxemic hypoxia (states characterized by the potential or actual documentation of tissue hypoxia despite a normal PaO$_2$ such as carbon monoxide [CO] poisoning), (e) the perioperative and postoperative states, and (f) cluster headaches [3,84,85]. Additionally, oxygen should be administered empirically in cases of cardiac or respiratory arrest, respiratory distress, hypotension, shock, and severe trauma [3].

A dosage sufficient to correct the hypoxemia should be prescribed. The goal of oxygen therapy is to correct hypoxemia to a PaO$_2$ greater than 60 mm Hg or arterial oxygen saturation (SaO$_2$) greater than 90%. Owing to the shape of the oxyhemoglobin dissociation curve, there is little benefit from increasing the PaO$_2$ to values much greater than 60 mm Hg, and in some cases, it may increase the risk, albeit small, of CO$_2$ retention [3].

Clinicians are cautioned regarding the haphazard use of oxygen, because there are potential complications associated with the administration of supplemental oxygen, particularly at high concentrations (e.g., FiO$_2$ > 0.50). Oxygen therapy should not be used in place of but in addition to mechanical ventilation when ventilatory support is indicated [84].

Respiratory Failure. Oxygen therapy is used in acute pulmonary conditions to prevent tissue hypoxia and the serious and often irreversible effects on vital organ function that can result from untreated hypoxemia. In the absence of hypercarbia, the risk of worsening alveolar hypoventilation with the administration of supplemental oxygen is essentially nonexistent. Even among patients with chronic hypercapnic respiratory failure, the administration of supplemental oxygen to achieve a PaO$_2$ of approximately 60 mm Hg is associated with only a small risk of worsening hypercapnia. The mechanism by which oxygen administration results in CO$_2$ elevation among patients with COPD is multifactorial. It cannot be explained solely by the effect of oxygen on ventilatory drives. It
may also be due to an oxygen-induced increase in dead space resulting from relaxation of hypoxic vasoconstriction, and it also requires the presence of other respiratory abnormalities preventing compensatory hyperventilation [3]. Furthermore, in acute situations in which supplemental oxygen is necessary to maintain adequate tissue oxygenation, it should not be withheld even if there is a risk that ventilatory support may be required. Care should be taken, however, to avoid the administration of excessively rich oxygen mixtures. See Chapter 173 for further discussion of oxygen therapy in COPD.

**Acute Myocardial Infarction Without Respiratory Failure.** Based on studies demonstrating that breathing enriched oxygen mixtures limited infarct size in animals, it has become common practice to administer oxygen to patients suspected of experiencing ischemic-type chest discomfort [84]. Because nitroglycerin dilates the pulmonary vascular bed and increases ventilation–perfusion abnormalities, supplemental oxygen has been recommended during nitroglycerine use and for the initial hours after an acute MI is first suspected. Experimental studies have shown that supplemental oxygen may limit ischemic myocardial injury [86,87] and reduce ST-segment elevation among patients experiencing a MI [88]. The routine use of supplemental oxygen, however, may be associated with an increased risk of death, questioning this practice [86,87]. In the setting of MI complicated by left ventricular failure, arrhythmias, or pneumonia, the appropriate oxygen concentration should be determined by monitoring of the PaO₂ or SaO₂ [84]. Supplemental oxygen should be administered to maintain an SaO₂ goal greater than 90% [84].

**Acute Asthma.** Supplemental oxygen protects against hypoxemia resulting from pulmonary vasodilation induced by β agonists and minimizes hypoxemia-induced vasoconstriction [89]. Normal levels of oxygen (normoxia) may protect against cardiac arrhythmias and may also help oxygen delivery to peripheral tissues [3].

Supplemental oxygen is recommended for patients with hypoxemia and for patients with FEV₁ or peak expiratory flow less than 50% of the predicted value during an acute attack when arterial oxygen monitoring is not available. The National Asthma Education and Prevention Program Expert Panel Report 3 recommends oxygen administered via nasal cannula or mask to maintain an SaO₂ greater than 90% (greater than 95% in pregnant women and in patients with a history of heart disease) [13]. SaO₂ monitoring should continue until a definite response to bronchodilatory therapy occurs.
**Normoxemic Hypoxia.** *Normoxemic hypoxia* encompasses conditions that are characterized by the potential or actual documentation of tissue hypoxia but with a normal PaO₂ [84]. Tissue hypoxia occurs as a result of abnormal hemoglobin function, deficient delivery, or inefficient use of oxygen by the tissues. Examples of such conditions include acute anemia, carboxyhemoglobinemia (perhaps the most lethal), and sickle-cell crisis.

Recommendations for the use of supplemental oxygen for normoxemic hypoxic conditions are outlined as follows:

1. *Acute anemia.* Although the definitive treatment is sufficient blood replacement, supplemental oxygen is a reasonable temporizing measure.

2. *Carboxyhemoglobinemia* (CO poisoning) [3]. Because a partial pressure of CO of less than 1 mm Hg can saturate 50% of hemoglobin and not interfere with lung function, measurements of oxygen tension are not useful for predicting the presence of CO poisoning or for directing oxygen therapy. Carboxyhemoglobin levels must be measured to detect CO poisoning. Administration of high concentrations of inspiratory oxygen is important when treating CO poisoning for two reasons: a higher amount of oxygen may be placed in the solution in the blood to supplement the oxygen already present, and a high PaO₂ accelerates the dissociation of CO from hemoglobin.

   In the absence of hyperbaric oxygen, a nonrebreathing mask driven by pure humidified oxygen is the treatment of choice. This should be given immediately and without interruption until it is verified that carboxyhemoglobinemia has fallen to less than 5%. Although hyperbaric oxygenation represents a potentially more effective alternative, it is not readily available for most patients. If it is available, patients with carboxyhemoglobin levels greater than 40% or with cardiac or neurologic symptoms should be considered for immediate transportation to a hyperbaric oxygen facility for treatment. (See Chapter 178 for further discussion of CO poisoning.)

3. *Sickle-cell crisis.* The role of oxygen therapy for sickle-cell crisis is unknown [90]. Because deoxygenation makes cells sickle, however, it seems reasonable to give supplemental oxygen in this setting. Because of the risk of oxygen toxicity, concentrations in excess of 50% should not be given for more than 48 hours.

4. *Cluster headache.* Several trials have shown that oxygen delivered at rates between 6 and 12 L per minute can reduce acute pain from cluster headaches [91]. Supplemental oxygen is a first-line therapy along with injectable triptans. The mechanism of action for oxygen
therapy in this setting is unknown.

**Prevention of Surgical Wound Infections.** Routine perioperative administration of supplemental oxygen, regardless of the patient’s SaO_2_, may be advantageous in reducing the incidence of postoperative surgical site infections. The effect is more pronounced among patients undergoing colorectal surgery [92].

**Postoperative State.** An increase in the alveolar-arterial partial pressure of oxygen [P(A-a)O_2_] gradient and a decrease of the functional residual capacity are common perioperatively and postoperatively. Ventilation–perfusion abnormalities and intrapulmonary shunting may occur, and while generally corrected within the first few hours after most types of surgery, it may be more significant among the elderly, the obese, for patients with pre-existing cardiopulmonary conditions, and after surgery of the upper abdomen and thorax. For these situations, PaO_2_ may not normalize until postoperative Day 2. Because the PaO_2_ usually increases with the administration of supplemental oxygen, low concentrations of supplemental oxygen should be administered to those at risk of postoperative hypoxemia [93]. In some cases, lung-expansion maneuvers may be necessary after oxygen fails to correct the PaO_2_ [82].

**Oxygen Delivery Systems**

In the acute setting, bulk supply systems are used as a relatively inexpensive means of oxygen delivery. When transporting hospitalized patients, gas cylinders and liquid tanks are used.

**Oxygen Delivery Devices**

A variety of devices are available to deliver supplemental oxygen. Selection should be based on the amount of oxygen the system can deliver and its clinical performance. Factors capable of affecting performance include the type of device chosen, flow rates used by the device, the fit of the device, respiratory rate, inspiratory flows, and tidal volumes. Types of devices are as follows:

1. Standard dual-prong nasal cannulas are the most commonly used
oxygen delivery devices for administering low-flow oxygen. Flow rates of 0.5 to 1.0 L per minute by nasal prongs approximate an inspired oxygen concentration of 0.24, and a rate of 2 L per minute approximates 0.28. Nasal cannulas are easy to use, relatively comfortable, fairly unobtrusive, do not interfere with eating or talking, and relatively inexpensive. Generally, it is unnecessary to humidify oxygen administered by nasal cannulae at flow rates of 4 L per minute or less [84].

2. Simple oxygen masks deliver FiO₂ of approximately 0.35 to 0.50 oxygen with flow rates of 5 L per minute or greater. Because nasal cannulas and simple oxygen masks deliver an overlapping range of FiO₂, the nasal cannulas should be used unless the nares are unavailable or prone to irritation from the cannula. Face masks must be removed when eating and drinking, and caution should always be exercised when using oxygen face masks for sedated, obtunded, or restrained patients. Because these masks have a reservoir of 100 to 200 mL, there is a risk of rebreathing CO₂. For this reason, flow rates of at least 5 L per minute are recommended. Because relatively high-flow rates are needed with simple masks, they are generally not appropriate for the delivery of a low FiO₂ (e.g., less than 0.30 to 0.35) [84].

3. Masks with reservoir bags, nonrebreathing and partial-rebreathing oxygen masks, can deliver a high FiO₂ (>0.50) with oxygen flowing into the reservoir at 8 to 10 L per minute to partially inflate the reservoir bag throughout inspiration. They are designed to deliver short-term high FiO₂ for situations when hypoxemia is suspected [94]. After the patient has been stabilized, if a high FiO₂ is required, a fixed performance device with a known FiO₂ should be substituted. Theoretically, the partial-rebreathing mask should deliver an FiO₂ of approximately 0.60, and the nonrebreathing mask should deliver 1.00. For the nonrebreathing mask to deliver an FiO₂ of 1.00, however, a tight-fitting mask is required.

4. A Venturi-type mask can be used if an accurate FiO₂ is required. Supplied by high oxygen flows, it maintains a fixed ratio of oxygen to room air so that the FiO₂ remains constant. These masks can deliver oxygen concentrations to the trachea of up to 0.50. Venturi-type masks have been designed to deliver FiO₂ settings of 0.24, 0.28, 0.31, 0.35, 0.40, and 0.50.

5. High-flow nasal cannula (HFNC) oxygen administers heated and
humidified oxygen up to 60 L per minute. The physiologic consequences of HFNC include the application of a small amount of PEEP to the upper airway, an improvement of physiologic dead space, and improved work of breathing and oxygenation when compared to facemask oxygen for patients with hypoxemic respiratory failure. In a recent trial, while patients with nonhypercapneic respiratory failure treated with HFNC had equal rates of intubation as those treated with standard oxygen therapy and NIPPV, they had a better 90-day survival [95]. Clinical aspects of the use of HFNC such as who most benefits and when to escalate therapy remain undetermined.

**Oxygen-Conserving Devices**

Several devices have been developed to improve the efficacy of oxygen delivery. Three such methods are reservoir cannulas, demand-pulse oxygen delivery, and transtracheal catheters [3].

1. The reservoir nasal cannula stores 20 mL of oxygen during exhalation and delivers this oxygen as a bolus at the start of inspiration.
2. Electronic demand devices deliver a pulse of oxygen during early inspiration rather than continuously throughout the ventilatory cycle.
3. Transtracheal catheters bypass the anatomic dead space, and oxygen is delivered directly into the trachea using the central airways as a reservoir for oxygen during end-expiration [3]. When caring for patients with transtracheal catheters in place before admission to the hospital, it is important to secure them with tape or sutures to prevent accidental dislodging. There is no need to remove the catheter before or during endotracheal intubation. Although the patient is intubated, however, the transtracheal catheter should be capped.

Patients receiving transtracheal oxygen are at risk of developing inspissated secretions, mucus airway casts, and mucus balls, especially when the transtracheally delivered gas is not adequately humidified. Consequently, whenever a patient receiving transtracheal oxygen develops worsening hypoxemia or respiratory distress, mucus obstruction of the airway should be considered. In this setting, oxygen should be administered via nasal cannula and the transtracheal catheter removed. This maneuver can often shear off a mucus ball attached to the end of the catheter, allowing the patient to expectorate the accumulated mucus, and thereby improve the hypoxemia and eliminate the respiratory distress. The catheter can then be cleaned and reinserted with provision for adequate humidification of the transtracheally delivered gas.
Choice of Oxygen Delivery Device

For the hypercapnic, hypoxemic patient, therapy can begin with 0.5 to 2.0 L per minute by nasal cannula or 0.24 to 0.28 FiO₂ by Venturi-type mask. If the PaO₂ remains less than 55 mm Hg 30 minutes later, administration of progressive increments of inspired oxygen is undertaken. Assessment of gas exchange is measured at frequent intervals, usually every 30 minutes [3] for the first 1 to 2 hours or until it is certain that the PaO₂ is 55 mm Hg or greater and CO₂ narcosis is not developing. In the hypercapnic patient, titration of supplemental oxygen is best assessed by arterial blood gas analysis rather than oximetry because the arterial blood gas provides PaCO₂ and oxygenation data. An initial modest increase in PaCO₂ (5 to 10 mm Hg) is expected in most hypercapnic patients given supplemental oxygen [96].

If a well-fitted Venturi-type mask delivering FiO₂ of 0.50 fails to achieve an oxygen saturation of at least 90% or a PaO₂ of 60 mm Hg or greater, the patient usually has severe cardiogenic pulmonary edema, ARDS, overwhelming pneumonia, or a cardiac or pulmonary vascular shunt. In these settings, a nonrebreathing mask is recommended for two reasons. First, when properly worn, it has the potential to deliver the most predictable oxygen concentration (close to 100%) of all the high-concentration delivery mask devices (e.g., aerosol masks, partial rebreathing masks, or face tents). Second, it can reveal the presence of a right-to-left shunt. If the PaO₂ is 60 mm Hg or less in the face of a fractional concentration of inspired oxygen of close to 1.00, a right-to-left shunt of approximately 40% of the cardiac output is present. An alternative acceptable oxygen delivery method in this scenario is a high-flow nasal cannula. If the patient does not respond to these initial noninvasive modes of oxygen delivery, invasive mechanical ventilation should be considered.

Oxygen therapy should never be abruptly discontinued when hypercapnia has worsened and CO₂ narcosis is a possibility. This causes PaO₂ to fall to a level lower than it was before any oxygen was given [3] because the patient is breathing in a slower, shallower pattern.

Long-Term Continuous Oxygen Therapy
Continuous (24-hour) oxygen therapy significantly prolongs and improves the quality of life in hypoxemic patients with COPD [3]. If used for 15 hours per day or more, it decreases mortality by 1.5- to 1.9-fold over the subsequent 3 years. Patients who should be given continuous oxygen during hospitalization and as outpatients include those with a PaO$_2$ of 55 mm Hg or less and those with a PaO$_2$ of 59 mm Hg or less plus peripheral edema, hematocrit of 55% or greater, or P pulmonale on electrocardiogram. Because many of these patients continue to improve as outpatients, the need for continuous oxygen therapy should be reassessed at 1 month [97].

**Complications of Oxygen Therapy**

Among adults, decreased mucociliary clearance, tracheobronchitis, and pulmonary oxygen toxicity are the major complications of oxygen therapy. Mucociliary clearance is decreased by 40% when 75% oxygen is breathed for 9 hours and by 50% when 50% oxygen is breathed for 30 hours [3]. Symptomatic tracheobronchitis is caused consistently by the inhalation of high concentrations of oxygen (0.90 or higher) for 12 hours or more; it is manifested by substernal pain, cough, and dyspnea [3].

To avoid clinically significant pulmonary oxygen toxicity, prolonged administration of concentrations greater than 0.50 should be restricted, whenever possible, to 48 hours [3]. The pathology of oxygen toxicity is that of ARDS; it can lead to death from refractory and progressive hypoxemia due to interstitial fibrosis. It is best avoided by restricting delivery of oxygen to the lowest concentration and shortest duration absolutely necessary to achieve a satisfactory PaO$_2$. Therefore, prophylaxis consists of using any and all measures that allow a decrease in the concentration of inspired oxygen to subtoxic levels. PEEP has been shown to be useful for achieving this goal.

For patients with previous bleomycin exposure, there appears to be a synergistic effect with subsequent exposure to high concentrations of inspired oxygen, resulting in the development of bleomycin associated pneumonitis [98]. Although it is unclear how long after bleomycin exposure that breathing high-inspired oxygen concentrations predisposes to pneumonitis, the risk appears highest within the first 6 months of bleomycin exposure.

A similar interaction can be seen among patients taking long-term amiodarone and exposure to high concentrations of inspired oxygen [99]. This risk appears higher for patients receiving high concentrations of inspired oxygen via mechanical ventilation. These patients can develop diffuse alveolar damage and ARDS, and mortality rates may be as high as 33% [100]. For patients with a history of either bleomycin or amiodarone exposure, we recommend using the lowest amounts of supplemental
oxygen possible to maintain adequate oxygenation.

Although the complications of retrolental fibroplasia and bronchopulmonary dysplasia from oxygen toxicity have been limited in the past to pediatric patients, reports of adults with bronchopulmonary dysplasia, the eventual result of ARDS, have appeared [3]. Central nervous system dysfunction manifested by myoclonus, nausea, paresthesias, unconsciousness, and seizures is limited to hyperbaric oxygenation at pressures in excess of 2 atm [3].

### Hyperbaric Oxygen Therapy

Hyperbaric therapy, 100% oxygen at 2 to 3 times the atmospheric pressure at sea level, is used as primary therapy in the treatment of patients with decompression sickness, arterial gas embolism, and severe CO poisoning [3]. In the case of CO poisoning, although hyperbaric therapy accelerates the resolution of symptoms, it does not appear to affect the rate of late sequelae or long-term mortality for non–life-threatening cases [3]. It is used as adjunctive therapy with supportive evidence in the treatment of crush injuries, clostridial myonecrosis/necrotizing fasciitis, compromised skin grafts, refractory osteomyelitis, and necrotizing skin infections [101]. Other conditions that may benefit from hyperbaric oxygen therapy include traumatic brain injury, acute ischemic stroke, acute coronary syndrome, and diabetic wounds. Data are inconclusive and further study is required [102–105].

### Helium-Oxygen (Heliox)

Because helium is less dense and has a lower molecular weight than nitrogen, it often improves flow where airflow is turbulent (i.e., density and molecular weight dependent). However, this primarily occurs in large airways when there is tracheomalacia, laryngeal edema or an upper airway–obstructing lesion. Heliox has successfully decreased airway resistance for patients with postextubation upper-airway obstruction [3], for children with severe croup who were refractory to inhaled racemic epinephrine [106,107], and for upper-airway obstruction due to tracheal tumors or extrinsic compression [108]. Although there have been favorable physiologic effects shown by a number of randomized controlled trials of spontaneously breathing patients with acute severe asthma [3], one large meta-analysis of seven studies [109] and an extensive review by the Cochrane Database [110] failed to show any benefit of routinely using Heliox for the management of acute asthma patients. At this time, there is no definitive evidence to support the use of Heliox for the treatment of asthma exacerbations. Heliox has been used with nebulized albuterol for the treatment of asthma, but any benefit is unclear as there are conflicting results in the literature [111–113].
The effect of increasing concentrations of helium for decreasing airway resistance is linear, but most reduction has taken place when the concentration of helium approaches 40% [114]. Therefore, Heliox mixtures should contain a minimum of 40% helium, with the balance of the mixture being oxygen. For patients in respiratory distress with little hypoxemia due to laryngeal edema, a Heliox mixture of 80% helium and 20% oxygen would suffice. For patients in respiratory distress with hypoxemia due to pulmonary edema associated with laryngeal edema, however, a Heliox mixture of 40% helium and 60% oxygen would be most advantageous.

In an uncontrolled trial, intubated patients with status asthmaticus on mechanical ventilation [115] were successfully ventilated with a mixture of 60% helium and 40% oxygen and experienced a decrease in airway pressures and PaCO$_2$ and resolution of acidosis. Others report improvements of airway mechanics among mechanically ventilated patients using an oxygen and helium mixture [116,117]. However, no definite improvement of outcomes were reported.

Because helium may affect how ventilators measure gas parameters, monitoring of ventilator outputs must be undertaken when helium is delivered through the ventilator.

Although Heliox may provide favorable short-term physiologic effects for patients with acute exacerbations of COPD [3], review of the literature has concluded that there is insufficient evidence to support the use of Heliox for the management of ventilated and nonventilated patients with acute exacerbations of COPD [118].

In summary, Heliox should only be considered a support modality that serves as a bridge, allowing specific therapies more time to work [3]. Only its use for the treatment of severe upper-airway obstruction and croup in children are supported by current studies. Current studies do not support its routine use in the management of acute exacerbations of COPD, asthma, or acute bronchiolitis among children. Nevertheless it is reasonable to consider the use of Heliox when conventional therapies have failed for patients with acute asthma or bronchiolitis.

**Nitric Oxide**

Inhaled NO is a potent, selective pulmonary vasodilator. Early studies reported the clinical application of inhaled NO in adult patients with primary pulmonary hypertension and since then, many trials have been conducted to identify additional applications [119]. Inhaled NO has been
investigated for a variety of other areas, including (a) ALI and ARDS, (b) status asthmaticus, (c) intestinal ischemia and reperfusion, (d) thrombotic disorders, (e) sickle-cell crisis, and sepsis-related microcirculatory dysfunction [3,120]. An extensive review of the use of inhaled NO therapy for adults can be found elsewhere [121]. The effectiveness of using NO for these conditions is questionable. Inhaled NO appears to only transiently improve oxygenation, increases the concentrations of toxic oxides of nitrogen in the airways, and does not appear to decrease mortality among patients with severe lung injury [122]. High cost, exposure to toxic metabolites, safety concerns, and lack of efficacy of inhaled NO has led investigators to explore other inhaled vasodilator therapies such as prostacyclins and nitrosothiols for the treatment of patients with severe hypoxemia related to ARDS [123]. Studies to date have failed to detect significant mortality benefits, therefore, the effectiveness of inhaled prostacyclins remains unconfirmed [124].
CONTINUOUS POSITIVE AIRWAY PRESSURE FOR SLEEP-RELATED BREATHING DISORDERS

CPAP is an effective treatment for clinically significant obstructive sleep apnea/hypopnea syndrome, sleep-related oxyhemoglobin desaturation, and respiratory event-related sleep arousals. This therapy can be delivered by nasal, partial, or full-face mask and is associated with improved morbidity due to reductions of daytime somnolence and improved cardiopulmonary function. Although further study of the long-term effects of CPAP is necessary, data suggest a possible reduction of mortality [125]. Since 1981, its efficacy has been repeatedly demonstrated [126]. Multiple controlled studies have shown that CPAP can also be effective for patients with chronic left ventricular failure and Cheyne–Stokes respirations [3]. Among these patients, CPAP improved cardiac function and alleviated symptoms of heart failure and sleep-disordered breathing. CPAP has been shown to reverse central sleep apneas for some patients [127]. Simple snoring that is not associated with pauses in respiration or with clinical impairment is generally not treated with CPAP [127]. The use of CPAP and bilevel positive airways pressure (BiPAP) for the management of patients with acute respiratory failure is discussed in Chapter 167.

Application

CPAP acts as a pneumatic splint to prevent upper airway collapse. Patients usually respond rapidly to 3 to 15 cm H$_2$O. The minimal effective CPAP pressure is determined during a nocturnal polysomnogram during which pressure is titrated upward until sleep-related breathing events are eliminated [128]. Lack of response is often due to a poorly applied mask or patient intolerance [129]. Compliance rates can vary considerably (46% to 89%) [128].

Multiple delivery devices are available that may improve patient comfort, including a variety of nasal, partial, and full-face masks. Nasal pillows or the Helmet device can also be used to deliver CPAP. Rare serious complications [129] include bilateral bacterial conjunctivitis, massive epistaxis due to drying of the nasal mucosa of a patient with coagulopathy, and worsening obstruction among patients with large lax epiglotti.

Because CPAP is very effective, safe, and reasonably well tolerated, it
has become the technique of choice for the treatment of idiopathic obstructive sleep apnea (i.e., no correctable anatomic abnormality identified). Relative contraindications include the presence of bullous lung disease or recurrent sinus or ear infections. There are no absolute contraindications [3]. It is important to realize that uvulopalatopharyngoplasty may compromise CPAP therapy by increasing mouth air leak and reducing the maximal level of pressure that can be tolerated, and it benefits only some patients [130].

**Alternative Modalities**

For patients with sleep apnea/hypopnea syndrome who cannot tolerate nasal or full-face mask CPAP because of the sensation of excessive pressure, nasal or full-face mask bilevel ventilation may be more tolerable. This permits independent adjustments of inspiratory positive airway pressure and expiratory positive airway pressure, setting a respiratory rate, and can eliminate sleep-disordered breathing at lower levels of expiratory airway pressure compared with conventional CPAP therapy for selected patients [3].
Anxiety and fear are common emotions experienced by patients during mechanical ventilation. These emotions have been associated with the experience of agony/panic and insecurity related to the inability to communicate [131]. Patients with endotracheal and tracheostomy tubes in place experience these feelings because the tubes interfere with normal verbal communication. Providing a means of communication for patients undergoing mechanical ventilation has been shown to significantly increase patient satisfaction [131].

Intubation with cuffed, inflated intratracheal tubes impairs verbal communication because they block the normal airflow through the vocal cords. Deflated cuffed or cuffless tubes, generally reserved for spontaneously breathing patients, allow verbal communication, provided there is no pathologic obstruction (e.g., edema and granulation tissue or excessive secretions) blocking the passage of air through or above the vocal cords.

Communication Aids and Devices

A variety of communication aids are available depending on the situation [132]. A speech therapist can be extremely valuable for helping to select which aid is best for your patient.

Partial cuff deflation methods can be used for nonventilator-and ventilator-dependent patients. They are most commonly used in the nonventilator situation. Their use in the ventilator situation requires extremely close monitoring of the patient along with ventilator adjustments.

In the nonventilator-dependent patient, one can use deflation of the tracheostomy cuff with intermittent gloved finger occlusion of the tube or a device with a one-way valve (e.g., Passy-Muir Valve [PMV], Passy-Muir, Inc., Irvine, CA). The PMV is a one-way, positive-closure, no-leak valve that attaches to the hub of tracheostomy tubes (including cuffless fenestrated and nonfenestrated tubes, metal tubes, and cuffed tubes with the cuff fully deflated) [133]. It is indicated for awake and alert tracheostomy patients who can generate sufficient air flow around the tracheostomy tube (or through a fenestrated tube) and through the vocal
cords. When the patient inhales, the PMV opens, allowing air to enter the lungs through the tracheostomy tube. As exhalation begins, the PMV closes, and remains closed through exhalation so that air is redirected around the tracheostomy tube or through the tracheostomy tube fenestra (window), allowing for speech as the air passes through the vocal cords. Oxygen can be administered with the PMV in place at the tracheostomy tube site via oxygen mask, trach collar, or O₂ adapter. When using the PMV with tracheostomy tubes that have an inner cannula grasp ring that extends beyond the external end of the hub of the tracheostomy tube, the inner cannula should be removed when the PMV is in use to avoid obstruction of the valve’s diaphragm movement.

For the ventilator-dependent patient, one can use partial deflation of the tracheostomy cuff alone or the one-way valve with full cuff deflation. During mechanical ventilation, both methods require close monitoring of the patient and the ventilator. Because use of the PMV with ventilator-dependent patients requires the cuff to be deflated, adjustments of the tidal volume may be necessary to offset the volume loss caused by the air leak. Contraindications to the use of the one-way valve include the presence of an inflated cuff, absolute necessity for the cuff to remain fully inflated, tracheal/laryngeal obstruction, or secretions preventing air from moving around or above the tube, laryngectomy, bilateral vocal cord paralysis, unconsciousness, and physiologic instability [3]. Use of the valve with an inflated cuff can result in breath stacking with resultant intrinsic PEEP and barotrauma [134]. Because less-exhaled volume is returned to the ventilator with the deflated cuff methods, ventilator-exhaled volume alarms have to be adjusted [135]. Lack of intact oral and laryngeal musculature for some patients with neuromuscular diseases may preclude effective use of the valve [135].

The electronic larynx is a handheld mechanical device that can be used by patients who have undergone laryngectomy. When pressed into the soft tissue of the neck, it generates a vibratory sound that escapes through the mouth and is articulated by the lips, tongue, and palate. Its disadvantage is the metallic-type sound that is produced [136]. The Blom–Singer tracheostoma valve (Forth Medical Ltd., Berkshire, UK) is available for prosthesis-assisted tracheoesophageal speech in postlaryngectomy voice rehabilitation [137]. Finally, a variety of computer-assisted communication devices and electric typewriters are available, but are usually considered for patients requiring long-term mechanical ventilation because of their complexity and expense [3].

Advances of respiratory adjunct therapy, based on randomized controlled trials or meta-analyses of such trials, are summarized in Table 169.1.

Aspiration is defined in *Webster’s New Universal Unabridged Dictionary* as inhaling fluid or a foreign body into the bronchi and lungs [1]. The foreign material may be particulate matter, irritating fluids (e.g., HCl, mineral oil, animal fat), or oropharyngeal secretions containing infectious agents. Although infectious pneumonias can be caused by inhaling aerosolized infectious organisms, aspiration of oropharyngeal contents or regurgitated gastric material is the primary manner in which bacterial pathogens are introduced into the lower respiratory tract. In fact, studies indicate that 7% to 24% of cases of community-acquired pneumonia are aspiration pneumonia [2]. The term *aspiration pneumonia* strongly denotes infectious sequelae as a result of aspiration of oropharyngeal secretions colonized by pathogenic bacteria. However, there is a wide spectrum of conditions that result from aspirating foreign matter with varying clinical courses, not all of which are caused by infection [3–5]. It is difficult to predict exactly which course a patient will follow after an event. Although aspiration of a large volume of sterile gastric contents will likely lead to a chemical pneumonitis, aspiration of contaminated gastric contents will more likely result in an infectious pneumonia. Although the frequency of all clinically significant aspirations in the intensive care unit (ICU) setting is not known, a review of Table 170.1 suggests that aspiration syndromes are common causes of respiratory failure in the critically ill patient.

NORMAL DEFENSES AGAINST ASPIRATION AND THE MANNER IN WHICH THEY MAY FAIL

Pathogenesis

Syndromes caused by aspiration are determined by (a) the material aspirated, (b) the amount aspirated, and (c) the state of the patient’s defenses at the time of the event. An understanding of the normal defenses and how and when they become impaired is also the cornerstone for an understanding of the pathogenesis of the various aspiration syndromes.

Because gastric acid prevents bacterial growth, the gastric contents are sterile under normal conditions. Nevertheless, it has long been thought that the pH of aspirated contents determined the clinical course, with lower pH aspirates portending a worse outcome. Elevation of gastric pH to protect the lung was cited as one reason to use prophylactic antacids for the critically ill patient. However, colonization of the stomach by pathogenic organisms may occur when the gastric pH is artificially elevated [6]. There is conflicting data as to whether or not proton pump inhibitors and H₂ blockers increase the risk of pneumonia [7–9]. Use of medications for stress ulcer prophylaxis in the ICU is entirely another issue and is discussed in Chapter 204.

Upper Gastrointestinal Defenses

Gastrointestinal mechanisms normally work in a coordinated, synchronized fashion. The teeth break up large food particles, and the tongue propels fluid and masticated food into the hypopharynx. Because the hypopharyngeal muscles prepare to move food into the esophagus,
the epiglottis covers the laryngeal inlet and the vocal cords close and the upper esophageal sphincter (cricopharyngeus muscle) relaxes. Pharyngeal swallowing initiates primary peristaltic waves in the esophagus that carry fluid and food through a relaxed lower esophageal sphincter (LES) into the stomach. After the bolus enters the stomach, the LES then contracts and prevents, although not entirely, gastroesophageal reflux (GER).

Even in the absence of known trauma or a neurologic insult that could affect the swallowing cascade, some of the previously mentioned defenses may become impaired in a variety of situations, leading to silent aspiration. Aging can result in progressive loss of cough and swallowing reflexes resulting in aspiration pneumonia. The vocal cords close much more slowly after the age of 50 years and may not close at all during sleep or with sedation irrespective of age. Furthermore, the cough response to airway irritation is decreased during sleep compared to the waking state. It has been estimated that half of all healthy adults aspirate oropharyngeal secretions during sleep [3].

The risk of aspirating fluid and food is increased when the normal swallowing and upper gastrointestinal mechanisms fail to work in a coordinated, synchronized manner. Edentulous or neurologically impaired patients may not adequately masticate food resulting in higher aspiration risk. Aspiration also may occur when the bolus cannot readily be cleared from the pharynx owing to neuromuscular disorders of any cause [10]. Structural abnormalities such as Zenker’s diverticulum place a patient at risk of aspiration because the diverticulum may empty “late” after the swallowing effort is completed, at the time when the vocal cords are abducted. Conditions in which vocal cord closure becomes excessively delayed (e.g., aging, debilitation, sedation, the presence of a tracheostomy, and after endotracheal extubation) place patients at high risk for aspiration.

Regurgitation and subsequent aspiration of stomach contents also occur among elderly, sedated, or sleeping patients, especially when their upper esophageal sphincter and LES have been rendered incompetent by an oral or a nasogastric tube [11]. The risk of aspiration is enhanced when such patient remains in the supine position, a scenario often encountered in the ICU setting.

Respiratory Defenses
For infectious agents to enter the lower respiratory tract, they must be small enough (<10 μm) to escape aerodynamic filtration in the nose,
mouth, and larynx. Particles between 0.5 and 1.5 μm in diameter can reach the alveoli. This is particularly relevant because most bacteria are within this size range. Although mucociliary clearance removes the larger particles from the larger airways, additional defense mechanisms are needed to clear the smaller particles [12]. This is accomplished in respiratory bronchioles and alveoli primarily by the alveolar macrophages, aided by neutrophils [13]. Recent studies, utilizing newer, molecular biology, noncultural techniques, have revealed that the lungs have their own respiratory biome and may not be sterile as previously thought [14]. These results are consistent with chronic microaspiration during sleep, as mentioned earlier.

The first line of defense is mucociliary clearance. The respiratory filtration system and mucociliary clearance may become overwhelmed with large-volume fluid and food aspiration or with large amounts of inhaled infectious agents. Respiratory defenses may also become ineffective in the following settings: inhalational or systemic general anesthesia, endotracheal intubation, endotracheal suctioning, hypercapnia and hyperoxia, smoking, asthma, chronic bronchitis, cystic fibrosis and bronchiectasis, and respiratory infections with viruses and atypical organisms.

In the absence of mucociliary clearance, the airways can still be cleared of excessive secretions and foreign bodies if the patient has an effective cough. An effective cough generates a column of expired air moving quickly through the bronchi, thus dislodging mucus and debris from the bronchial mucosa and propelling it out of the lungs [14]. However, cough is not a primary defense mechanism and only provides clearance when mucociliary clearance is inefficient or overwhelmed. An effective cough is determined by both good expiratory flow rates and respiratory muscle strength. Thus, cough may be ineffective in patients with severe asthma, chronic obstructive pulmonary disease, respiratory neuromuscular disorders, painful incisions, or in those receiving excessive sedation and analgesia with antitussive effects [14].

When the mechanical airway defenses are overwhelmed, alveolar macrophages represent the initial phagocytic response. This response is followed by the influx of neutrophils into the alveolar spaces. Neutrophils are critical for the eradication of bacterial agents, and, therefore any impairment in their function would be detrimental [13]. Aspirated bacteria cause infectious pneumonia when the alveolar phagocytes become impaired, such as in alcoholism, pH less than 7.2, acute alveolar hypoxia, alveolar hyperoxia, corticosteroid therapy, respiratory viral infections, hypothermia, starvation, and exposures to nitrogen dioxide, sulfur dioxide, ozone, and cigarette smoking on a long-term basis [3].

Immunologic defenses such as complement, innate immunity proteins, and immunoglobulins augment the nonimmunologic mechanisms.
Patients with hereditary and acquired immunologic abnormalities, such as immunoglobulin G and complement deficiencies, are susceptible to frequent and often severe bacterial pneumonias.
PREVALENCE OF ASPIRATION AMONG THE CRITICALLY ILL

Aspiration is the leading cause of pneumonia among the critically ill [15] and should be considered for all ICU patients with respiratory symptoms. This is especially true for the elderly, debilitated, or sedated patient. Oral or nasal enteral feeding tubes that compromise the LES, medications that decrease gastric motility, history of dysphagia, and poor dentition increase the probability. The presence of an endotracheal tube or a tracheostomy tube poses a high risk for aspiration and its consequences.

Translaryngeal Intubation

Clearly, no one would feed a patient with an oral or a nasal endotracheal tube in place, given the obvious mechanical barrier and distortion of the swallowing structures. What is often less intuitive is that dysphagia may persist for a variable time after the endotracheal tube has been removed. The reported prevalence of postextubation dysphagia ranges from 3% to 84% [16]. Factors that increase the likelihood of dysphagia after extubation include intubation >48 hours; laryngeal edema; and ulceration, erythema, and immobility of the vocal cords. Furthermore, neuromuscular weakness, loss of sensation, delirium, sedation, gastroesophageal reflux disease (GERD), and disorganized breathing all contribute to aspiration risk [16]. Should aspiration occur, ciliary clearance and other respiratory defenses might not respond appropriately because of the physical insult of the endotracheal tube. Flexible endoscopic evaluation of swallowing (FEES) aids in the identification of patients who are at high risk of aspiration after endotracheal intubation [17–19]. Studies have suggested that performing an FEES within 24 hours of extubation is safe and can potentially provide results that lead to avoidance of placing a nasogastric tube [16].

Aspiration Risk After Tracheostomy

Patients with a tracheostomy tube, with or without dependence on mechanical ventilation, are also at high risk for aspiration. The most commonly identified reasons for swallowing dysfunction for the patient with a tracheostomy tube are incomplete backward folding of the epiglottis, not allowing the glottis to rise and tilt forward with swallowing, pharyngeal retention, penetration, and aspiration [15]. The application of a speaking valve can restore subglottic air pressure and reduce aspiration
and penetration [20].

**Enteral Feeding Catheters**

Many patients in an ICU have nasal or oral gastric tubes for nutritional support. The mere presence of an orogastric- or a nasogastric feeding tube increases the risk of reflux and aspiration by compromising the integrity and proper functioning of the LES by two mechanisms. First, the catheter prevents closure of the sphincter by direct mechanical interference. Second, the irritation of the pharynx by the tube promotes LES relaxation through vagally mediated pharyngeal mechanoreceptors [21]. In addition, the presence of a nasogastric feeding tube is associated with gram-negative bacterial contamination of the oropharynx, which, when aspirated, can result in infection of the lower airways [22].

Varying the size of the enteral feeding catheters and adjusting the location of the distal tip have been used in an attempt to minimize aspiration. However, decreasing the size of a nasal or an oral tube for enteral feeding does not reduce GER or microaspiration events [23]. Small-bore feeding tubes appear to provide no added benefit with respect to reflux events, even when advanced to the postpylorus position [24].

Patients with long-standing swallowing defects or on prolonged mechanical ventilation may be candidates for percutaneous gastrostomy or jejunostomy tubes; however, even percutaneous enteral feeding tubes alter lower esophageal tone and can allow reflux. This manner of enteral feeding is not completely protective against aspiration despite bypassing the LES. In fact, patients fed by gastrostomy tubes have the same incidence of pneumonia as those fed by nasogastric tubes [25,26]. Furthermore, although a percutaneous jejunostomy tube may minimize the large-volume aspiration events, it is a misconception that it prevents aspiration or decreases its incidence relative to a percutaneous gastrostomy tube [27].

There is little agreement over what constitutes excessive gastric residual volumes that place a patient on enteral feeds at increased risk of aspiration. In fact, one study showed that the absence of monitoring gastric residual volume was noninferior to residual gastric volume monitoring in terms of ventilator-associated pneumonia prevention. Additionally, there was less prokinetic drug use and improved nutrition in the nonmonitored group [28,29].
DIAGNOSIS OF AN ASPIRATION SYNDROME

Aspiration syndromes are underdiagnosed and challenging to diagnose. Although signs of wheezing, shortness of breath, cyanosis, and hypoxia may be present, aspiration may also be completely asymptomatic. There is also a misconception that aspiration must be witnessed before it can be assumed to have occurred because many aspiration events are silent [30]. There has been increasing research with regard to use of biomarkers (e.g., pepsin in bronchoalveolar lavage fluid, presence of lipid-laden pulmonary macrophages, and procalcitonin) to aid with diagnosis and prognosis of an aspiration syndrome. Although most biomarkers are easy to measure, they lack specificity and sensitivity [30].

Bedside Evaluation

Table 170.2 outlines all the studies that may be necessary to diagnose aspiration syndromes accurately (see “Differential Diagnosis and Treatment” section). In addition to taking a history, performing a physical examination and observing the patient drink 3 ounces of water when appropriate can uncover a swallowing problem. Although the bedside evaluation is not sensitive, a pharyngeal problem may be evident by watching the patient cough, sputter, and tilt his or her neck and head in an unnatural posture when drinking the water. An absent gag reflex is not a useful predictor of aspiration because many healthy individuals who do not have a gag reflex can swallow normally [31].

The order of when and in whom to order these tests depends on the patient populations and their presentations. FEES, flexible endoscopic evaluation of swallowing; GE, gastroscopeal.

**Modified Barium Swallow/Video Fluoroscopy**

Although observing patients can be useful when there is obvious difficulty during swallowing, aspiration is often silent in the critically ill patient. The incidence of silent aspiration in stable patients receiving long-term mechanical ventilation via a tracheostomy is high, between 63% and 77%, as determined by modified barium swallow/video fluoroscopy (MBS/VF) [32,33]. Therefore, bedside evaluation alone, particularly for these high-risk populations, is insensitive. Because of this, a negative bedside examination should be confirmed by a more objective method to evaluate aspiration for high-risk patients.

The MBS incorporates the use of barium with VF and has been available since the 1950s. It defines the pharyngeal anatomy with swallowing of a radiopaque contrast material, and the swallowed bolus is followed in “real time” under fluoroscopy. This allows for the identification of abnormal anatomy and physiology and the response to modifications in dietary consistencies and postural changes [17]. Various consistencies of barium are used with the MBS/VF evaluation, such as thin liquids, paste consistency, and solid food. Findings indicative of swallowing dysfunction that can be assessed by MBS/VF examination include premature leakage of oral contents into the pharynx, penetration of swallowed material into the nasopharynx during a swallow, retention of material in the valleculae and pyriform recesses, and laryngeal penetration and aspiration. In addition, the elevation and tilting of the larynx that accompanies a normal swallow can be observed easily. Lower esophageal diseases, such as reflux or obstruction, can also be observed using the MBS/VF study.

The MBS/VF examination, however, has multiple limitations. MBS/VF
is personnel intensive, requires transporting patients to the radiology department, and exposes patients to radiation. In addition, patients must adhere to a defined body position to accommodate the fixed fluoroscopy setup that may not be possible for all patients. The study is typically performed in the radiology department in the presence of a radiologist, radiology technician, and speech and language pathologist. Ideally, a speech pathologist should evaluate and accompany the patient to the examination so that specific recommendations can be made to prevent or minimize aspiration. Recommendations may consist of eliminating oral feeding or instituting various swallowing strategies such as the chin tuck, multiple swallows, turning of the head, or changing the consistency of solids and liquids.

**Flexible Endoscopic Evaluation of Swallowing**

Evaluation of swallowing under flexible endoscopic visualization has been shown to be sensitive in discerning a delay in swallowing initiation, penetration, aspiration, and pharyngeal residue [34–36]. The potential advantages include reduced cost and decreasing waiting time as compared with an MBS/VF evaluation. Patients avoid radiation exposure, and the examination can be performed at the bedside in varying body positions. FEES also allows visualization of pharyngeal secretions as well as identification of the source of the secretions that cannot be seen during MBS/VF. Potential risks associated with the procedure include gagging, laryngospasm, vasovagal syncope, topical anesthetic adverse reactions, and epistaxis. Furthermore, esophageal pathology and reflux cannot be concurrently evaluated as in MBS/VF.

FEES has now been extensively used in medical and surgical inpatients and, more specifically, in recently extubated ICU patients [16]. The decision to use MBS/VF versus FEES depends mainly on specific patient characteristics and available resources. Although there are some limitations of both approaches, both tests are comprehensive and show excellent agreement in diagnosing laryngeal penetration, aspiration, and pharyngeal residue, thus allowing for postural and dietary recommendations to decrease aspiration risk [17].

**Culture Evaluation**

Even when history or physical examination uncovers a swallowing defect, determining that an aspiration event has already occurred may also prove
challenging. Furthermore, an infectious process is not always established with each aspiration event. It is often difficult to distinguish between an inflammatory or “chemical” pneumonitis and an infection because both may present with fever, cough, and an infiltrate on a chest radiograph. If an infection is suspected, identification of the responsible organism is oftentimes elusive because routine expectorated sputum smears and cultures can be inaccurate. Specimens obtained from quantitative bronchoalveolar lavage or telescoping plugged catheters at bronchoscopy can help identify the lower respiratory tract infectious agent more accurately and are used preferentially, although they require an invasive procedure and moderate sedation. When accurate lower respiratory sampling techniques are used and the culture and smear results are negative for a patient who has not recently received antibiotics, an exogenous lipoid pneumonia or chemical pneumonitis must be considered.

Detection of Aspirated Enteral Feeds

With respect to bedside methods for detecting aspiration in tube-fed patients, two methods have predominated; however, neither test is sufficiently sensitive to be recommended and both are problematic. In the first method, blue food coloring or methylene blue is added to enteral feeds and the tracheal secretions are assessed for blue discoloration. Potential problems with this method include tissue absorption of the dye as well as increased risk of infection if the dye is contaminated. The second method tests tracheal secretions with glucose oxidase reagent strips for aspirated carbohydrates. The glucose method is nonspecific because varying concentrations of glucose have been recovered from tracheal secretions in nonfed, parenterally fed, and enteraly fed patients [37]. Therefore, the glucose test lacks specificity. Some FEES protocols involve mixing 1 mL of blue food coloring to both liquid and food to enhance visualization of the bolus, but studies have shown that this is not routinely required [17,19].
DIFFERENTIAL DIAGNOSIS AND TREATMENT

Treatment of the various aspiration syndromes should be prophylactic as well as specific. As previously mentioned, a formal speech and swallowing evaluation should be obtained whenever a swallowing condition is suspected or diagnosed. Specific recommendations can often be made to mitigate or eliminate aspiration from dysphagia. Precautionary rather than reactionary measures are likely to be far more effective, with less associated morbidity and mortality. However, the only preventive interventions that have been proven to be effective in the acute care setting are withholding oral feeding in sedated patients to prevent aspiration and elevating the head of the bed to at least 45 degrees to decrease GER and minimize subsequent aspiration [38,39].

A tracheoesophageal fistula is a rare complication resulting from injury to the posterior tracheal wall. This can occur from excessive endotracheal tube cuff pressure, direct injury during placement of a percutaneous tracheostomy, or erosion from the tip of a tracheostomy tube. For a mechanically ventilated patient, a tracheoesophageal fistula may present with increased secretions, evidence of aspiration of gastric contents, recurrent pneumonias, a persistent cuff leak, or severe gastric distention. Once a patient is extubated, the most frequent symptom is coughing after swallowing. The diagnosis can be made by bronchoscopy and esophagoscopy or by computed tomography scan of the mediastinum. Although definitive repair often requires surgical intervention, aspiration can be minimized by placing the cuff of the tracheostomy tube distal to the fistula [40].

Although a cuffed endotracheal tube does not offer complete protection against aspiration, all patients with severely altered consciousness with an enteral feeding tubes in place should be prophylactically intubated, whenever possible, for airway protection. Furthermore, once a patient is extubated, oral intake should not be resumed until an MBS/VF or FEES examination demonstrates swallowing competency [16]. Prophylactic antibiotics, corticosteroids, postpyloric feeding, gastric promotility agents, or gastric acid suppression cannot be routinely recommended at this time to prevent or minimize aspiration [3]. GERD with aspiration can be treated with a variety of measures, including head-of-the-bed elevation; a high-protein, low-fat antireflux diet; nothing to eat or drink for 2 to 3 hours before recumbency; no snacking between meals; acid suppression; and prokinetic drugs. If these measures fail, surgery with fundoplication can be effective. Oral hygiene should not be overlooked.
Routine oral care has the potential to decrease colonization with pathogenic bacteria. Tongue cleaning should be considered for the edentulous patient [41]. Oral care with topical chlorhexidine has not shown any significant reductions in the frequency of ventilator-associated pneumonia for most patient populations, and routine use is not recommended [42,43].

**Mendelson’s Syndrome**

Mendelson’s syndrome is synonymous with the acute respiratory distress syndrome (ARDS) [3] owing to the parenchymal inflammatory reaction caused by a large volume of aspirated liquid gastric contents. After an aspiration event, clinical status and radiographic changes progress within the next 24 to 36 hours. Contrary to the general view that gastric aspirates with pH greater than 2.5 are benign, the same syndrome can occur at a pH of 5.9 [44]. Patients who develop this syndrome invariably have a marked disturbance of consciousness that can occur from sedative drug overdose or general anesthesia that interferes with vocal cord protection. The subsequent clinical course can include death in 30% to 62% of cases. Once liquid gastric content aspiration has occurred and the ARDS has supervened, ventilatory and medical strategies appropriate for treating the ARDS become the focus of care. Despite their frequent use, parenteral corticosteroids have not been shown to be helpful [3]. Antibiotics are indicated only when the syndrome is complicated by infection.

**Foreign Body Aspiration**

Aspiration of solid particles causes varying degrees of respiratory obstruction. Most cases occur in children. When foreign bodies are inhaled into the tracheobronchial tree, 38% of patients give a clear diagnostic history, 22% give a history of an acute choking and coughing episode, and 40% complain of cough, dyspnea, and wheezing. Although the chest radiograph may demonstrate the foreign object, atelectasis, or obstructive emphysema, it is normal in 80% of the cases.

Food asphyxiation is obstruction of the upper respiratory tract caused by food, usually at the level of the hypopharynx. It may occur whenever and wherever people eat, including hospitalized patients. In restaurants, it is called the *café coronary* because it is often mistaken for a heart attack. Food asphyxiation should be suspected in middle-aged or elderly
patients with poor dentition or dentures that impair chewing adequately or in those sedated by alcohol or other drugs who attempt to swallow solid food. One key to a large foreign body aspiration that may obstruct the larynx or trachea is that the patient cannot speak. Particles that reach the lower respiratory tract and do not totally obstruct the trachea can be removed by coughing or bronchoscopically. Those that totally obstruct the trachea must be removed immediately by subdiaphragmatic abdominal thrusts sometimes followed by finger sweeps of the unconscious individual and chest thrusts in the markedly obese person and women in advanced stages of pregnancy [45].

Bacterial Pneumonia and Lung Abscess

Most bacterial pneumonias are a consequence of aspiration of oropharyngeal infectious material in association with impairment of lower respiratory tract defenses [41]. Preexisting gingival disease remains a prominent risk factor for anaerobic infections. The risk of aspiration pneumonia is lower among those with good oral hygiene. Initial studies from the 1960s to 1980s suggested anaerobes as the most common pathogens. However, we now find that aspiration pneumonia has a microbiologic spectrum that includes more *Staphylococcus aureus* and enteric gram-negative bacilli. Community-acquired pneumonia can occur when bacteria colonize the oropharynx prior to aspiration and are unable to be cleared by mucociliary clearance and detoxification by the alveolar phagocytes that have been rendered ineffective. Normal respiratory defenses and mucociliary clearance may be compromised by a preceding viral infection or underlying medical conditions that predispose to a bacterial “superinfection” [46]. Even the microbiology of abscesses has changed with the majority being due to aerobic (most commonly *Staphylococcus* species) organisms. Lung abscesses are now considered to be a result of more virulent community-acquired pneumonia pathogens and not because of aspiration of anaerobes alone [47]. The intubated patient is particularly susceptible to aspiration pneumonia because the endotracheal or tracheostomy tube bypasses the aerodynamic filtration protection of the upper respiratory tract and physically hinders mucociliary clearance. The intubated patient who requires a narcotic is at even greater risk because cough is also suppressed.

Once a bacterial pneumonia or lung abscess is suspected, the causative organism(s) should be identified and appropriate antibiotic therapy should be given (see Chapter 181).

Chemical Pneumonitis

Reminiscent of a chemical burn, airway and parenchymal injury may
develop after an aspiration event that triggers a cascade of inflammatory mediators [5,41]. Fever, cough, rales, sputum production, hypoxemia, and infiltrates on chest radiograph may all be presenting signs and symptoms that are nonspecific. What distinguishes this syndrome from the other aspiration sequelae, however, is the rapid, self-limited course and clinical resolution over several days without the need for antimicrobial therapy. However, it should be noted that patients can progress to fulminant ARDS. Infectious aspiration pneumonia may not be a primary event but may develop as a superinfection of aspiration-induced pulmonary injury, depending on the contents of the aspirated material and the patient’s underlying clinical condition.

**Exogenous Lipoid Pneumonia**

Exogenous lipoid pneumonia is the result of aspirating any kind of lipid or oil-based substance including mineral oil, animal oil (e.g., cod liver oil, milk products), vegetable oil, and formula feedings. Conditions more likely to be complicated by exogenous lipoid pneumonia include pharyngeal swallowing disorders, Zenker’s diverticulum, cricopharyngeal achalasia, scleroderma involving the esophagus, epiphrenic diverticulum, esophageal carcinoma, esophageal achalasia, and GERD [3]. Although patients with exogenous lipoid pneumonia usually do not appear toxic, the clinical presentation occasionally cannot be distinguished from that of acute bacterial pneumonia.

The important clues to the diagnosis must come from the history, physical examination, and upper gastrointestinal studies. The presence of food particles in a bronchoscopy specimen is diagnostic. Although fat stains performed on unfixed expectorated sputum, bronchoalveolar lavage specimens, or lung biopsy may reveal numerous lipid-laden alveolar macrophages, this finding only supports the diagnosis of exogenous lipoid pneumonia. Lipid-laden macrophages can also arise from an endogenous source or represent a nonspecific response of the lung to injury [3] because the lung is capable of making its own lipid. Quantitative cultures obtained with telescoping plugged catheters at bronchoscopy may be needed to rule out a bacterial infection, and lung biopsy may be needed to rule out cancer and to make the appropriate diagnosis. After the diagnosis is made, however, the inciting agent is usually identified with pointed questioning of patient practices.

If not diagnosed promptly, recurrent aspirations of lipid or small amounts of liquid gastric contents, or both, can present as recurrent hemoptysis, recurrent pneumonias, chronic interstitial fibrosis, bronchiolitis, or bronchiectasis [4]. Rarely, exogenous lipoid pneumonias are complicated by organisms of the *Mycobacterium fortuitum* complex [48]. Although corticosteroids may be helpful for cases of acute lipid
aspiration, acute exogenous lipoid pneumonias usually resolve on their own. The key to therapy is to prevent recurrences.

**Tracheobronchitis**

Tracheobronchitis must be considered not only for outpatients with GER and chronic, persistent cough [49] but also for hospitalized patients. Examples of conditions that predispose to an aspiration tracheobronchitis include a debilitated state, the postoperative period, endotracheal intubation, recent extubation, and neuromuscular diseases [3]. Aspiration tracheobronchitis should be suspected for patients with cough, wheezing, and bronchorrhea, defined as expectoration of more than 30 mL of phlegm in 24 hours. Treatment is the same as described previously in the “Exogenous Lipoid Pneumonia” section. In general, the bronchorrhea will disappear when oral intake is halted.

Chapter 171

Drowning
NICHOLAS A. SMYRNIOΣ • RICHARD S. IRWIN

OVERVIEW

Drowning is a process resulting in primary respiratory impairment from submersion/immersion in a liquid medium [1]. Implicit in this definition is that a liquid–air interface is present at the entrance of the victim’s airway, preventing the victim from breathing air. A victim can be rescued at any time during the drowning process and may not require an intervention or may receive appropriate resuscitative measures. The victim may live or die after this process [1]. Older terms, such as near-drowning, submersion or immersion injury, and dry or wet drowning are discouraged to facilitate clearer communication.

Drowning is the fifth most common cause of unintentional injury death in the United States [2]. It is the third most common cause of accidental injury death worldwide, claiming approximately 372,000 lives annually [3]. For most countries, drowning statistics do not include additional water-related deaths from boating accidents which are categorized separately. Therefore, some large-scale tragedies may be missed with these statistics. Drowning is most common among men, children younger than 14 years, North American Native populations, and African-Americans [2]. The states with the highest drowning rates are Alaska and Mississippi [4]. Statistics on nonfatal drowning are less exact because many nonfatal drowning victims do not seek medical attention. Estimates for the incidence of nonfatal drowning vary widely enough that a definitive statement cannot be made at this time.
ETIOLOGY AND PATHOGENESIS

The following are considered risk factors for drowning.

Alcohol

Ethanol use is the major risk factor for submersion accidents. In all, 30% to 70% of drownings are associated with alcohol consumption [5,6]. Alcohol use seems to be an issue for drowned men in particular [7]. Alcoholic beverages reduce the ability to deal with emergency situations by depressing coordination, increasing response time, and decreasing awareness of stimuli. Furthermore, alcohol consumption by a potential rescuer or by the adult responsible for supervising a child in the water can destroy that person’s ability to function effectively, often resulting in a double tragedy. In addition, alcohol is frequently a factor in drownings that result from automobile accidents.

Inadequate Supervision

Children die in water because adults do not supervise them well enough. The backyard pool and family bathtub are common sites of pediatric drownings [5,8]. Lack of appropriate precautions and supervision play a major role in most of these cases. Studies have shown lower rates of drowning for areas where swimming pools are required by law to be surrounded by a fence [2,5]. The fence must completely isolate the pool from unsupervised access by children to be effective. Diving and sliding headfirst may produce serious head and neck injuries as a result of striking the bottom or side of a shallow body of water. Appropriate sign posting in hazardous areas, effective educational programs on the dangers of water recreation, and the presence of lifeguards minimize risk and improve survival [5,9].

Inattentive caregivers also contribute to bathtub-related drownings. The use of infant bath seats, while providing some sense of security to parents, may actually predispose to submersion accidents because the child may slip and become trapped by the seat, making it impossible to escape the water [10]. The practice of leaving infants to bathe in the custody of a toddler is inappropriate and should be discouraged.

Child Abuse

Unfortunately, submersion injuries in children are sometimes inflicted intentionally. One study indicated that 29% of all nonfatal pediatric
drownings in bathtubs were purposely caused to inflict harm on the child. Another 38% of all nonfatal pediatric drownings revealed evidence of severe neglect [11]. In general, these children are younger than average for submersion injuries, and many have signs of previous abuse on close examination.

**Inadequate Swimming Skills**

Both objective data and common sense support the idea that improved swimming skill can reduce the risk of drowning. Although the exact magnitude of this reduction is imprecise, some reports have estimated it as high as 88% for young children [12,13]. This factor may be more pronounced among males who may overestimate their swimming ability [7].

**Seizures**

Drowning is 15 to 19 times more common in people with epilepsy than in the general population [14]. Poor adherence to anticonvulsant regimens often plays a role. A large percentage of drowning deaths in epileptics occur in bathtubs [15]. Seizures that include a tonic component may be the most dangerous to victims. Tonic seizures include a forced exhalation component that increases body density and causes the victim to sink. When the tonic component relaxes, the negative intrathoracic pressure leads to an inhalation that will then be composed of water [16].

**Boating Accidents**

Of the 710 boating fatalities in the United States in 2006, 70% were caused by drowning [17]. A blood alcohol level of 0.10 g per 100 mL is estimated to increase the risk of death associated with boating by a factor of 10 [6]. Failure to use personal floatation devices may also contribute to these deaths [18]. In addition, injuries associated with the use of personal watercraft share many features with boating accidents and are associated with drowning [19].

**Drugs**

Centrally acting drugs cause disorientation, induce sleep, impair coordination, and reduce the ability to swim. Data implicate both therapeutic medications and illegal drugs [20].
PATHOPHYSIOLOGY

General Considerations

Two mechanisms produce the major pathologic changes responsible for morbidity in drowning: anoxia and hypothermia.

Anoxia

Most drownings are thought to follow a common pattern [21]. The drowning sequence begins with a period of breath holding. This voluntary breath holding may be followed by an intense laryngospasm that prevents breathing. This laryngospasm is usually owing to water present in the pharynx or larynx. This prolonged inability to breathe renders the patient hypoxemic and hypercapnic. In almost every case, there are eventually involuntary breaths with aspiration of varying amounts of water. In addition, water may be swallowed that is eventually regurgitated and aspirated. Eventually, the victim becomes unconscious and cardiac arrest occurs.

Hypothermia

The impact of hypothermia is complex. Survival after extremely long submersion is generally considered possible only when the victim has been submerged in icy water. Most authors believe that to achieve such spectacular survivals after long submersions, the core body temperature must be reduced quickly and the brain’s metabolic activity slowed down in equally rapid fashion to prevent hypoxic damage to the brain. Factors that make this more likely for children include the increased relative body surface area, thin layer of subcutaneous fat, and smaller head size. In addition, children may aspirate water earlier after their submersion, and they may retain more water in the upper airway [22]. These factors may also play a role in rapid cooling. On the other hand, humans tolerate hypothermia poorly. In the most well-known example, the deaths after the sinking of the Titanic occurred not because of inability to float in most cases but because of hypothermia caused by exposure to extremely cold water. As if to highlight these contradictory effects of hypothermia on outcome, a recent study did not demonstrate any effect of water temperature on mortality [23].
Changes in human metabolism in response to hypothermia occur in two phases: the shivering phase and the nonshivering phase. Shivering occurs at a central temperature of 30°C to 35°C. The nonshivering phase occurs below 30°C, when muscle contractions nearly cease and oxygen consumption and metabolic rate decrease. Shivering and voluntary muscular movements, which in a cold dry environment work together to increase heat production with a minimal increase in heat loss, are ineffective in cold water. Both shivering and voluntary muscular movements increase blood flow to the extremities, thereby increasing conductive heat loss. Voluntary movements of the extremities also stir the surrounding water and can increase heat loss from convection. Body type may also play a major role. Water also nearly eliminates the insulative function of clothing by replacing the air between the fibers, thereby increasing heat conductance.

Submersion in very cold water can acutely lead to death. Hypothermia produces an increased tendency toward malignant arrhythmias. Cardiac arrest from ventricular fibrillation is common at core temperatures below 28°C, and asystole occurs at less than 20°C [24]. These arrhythmias may be refractory to resuscitative efforts until the body temperature has been increased. In addition, a decrease in core temperature can cause loss of consciousness and aspiration from the victim’s inability to keep the head above water. This leads to aspiration of water and the sequence of events described previously.

**Pulmonary Effects**

The effects of aspiration of various water solutions on lung injury have been studied in animals [9]. Decreases in arterial oxygen saturation and dynamic compliance as well as increases in minute ventilation, mean pulmonary artery pressure, and shunt fraction are seen after bilateral aspiration of either freshwater or seawater.

On a microscopic level, freshwater and saline solutions may cause their adverse pulmonary effects by different mechanisms. Atelectasis as a result of increased surface tension, bronchoconstriction, and noncardiogenic pulmonary edema all play a role in the development of hypoxemia at different times after freshwater aspiration [9]. Freshwater acts in part by inactivating surfactant in the alveoli and in part by damaging type-II pneumocytes, thereby preventing the production of surfactant. The combination of these effects may damage the alveolar capillaries and interstitium and lead to the acute respiratory distress syndrome (ARDS). Hypertonic seawater may draw additional fluid from the plasma into the alveoli, thereby causing pulmonary edema despite a decreased intravascular volume [9]. The fluid-filled alveoli are then unavailable for efficient gas transfer, and a ventilation–perfusion
mismatch occurs. Aspiration of gastric contents and particles in the water complicates both freshwater and saltwater drowning. Both saltwater and freshwater damage the alveolar–capillary interface and permit the influx of fluid into the alveolus. Therefore, in clinical practice, the difference between the injuries caused by freshwater and saltwater aspirations is small. In both cases, pulmonary edema causes decreased respiratory system compliance and hypoxemia.

Several other mechanisms of lung injury may occur with nonfatal drowning. Bacterial pneumonia, barotrauma, mechanical damage from cardiopulmonary resuscitation (CPR), chemical pneumonitis, centrally mediated apnea, and oxygen toxicity can cause respiratory deterioration in the postresuscitation period these must be considered along with ARDS in cases of respiratory distress occurring 1 to 48 hours after the event.

**Neurologic Effects**

The pathologic effects that most affect prognosis for drowning victims are related to the central nervous system. Cerebral injury is produced as a result of anoxia caused by gas exchange impairment and subsequent cardiopulmonary arrest.

Anoxic damage begins 4 to 10 minutes after cessation of cerebral blood flow in most situations [25]. The actual time course and clinical significance of anoxia in a specific drowning victim is notoriously uncertain because of the emotional condition of the witnesses and because the impact of hypothermia is difficult to judge. In addition, because drowning causes an asphyxial cardiac arrest, there will be persistence of perfusion for some time during the arrest that may provide some degree of protection from injury [25].

Many drowning victims suffer neurologic impairment. Victims display pathologic features similar to those of patients with anoxic encephalopathy from other causes, including diffuse cerebral edema, focal areas of necrosis, mitochondrial swelling, and other ischemic changes. These changes occur primarily in the cerebral cortex, hippocampus, and basal ganglia [25]. Severe anoxic encephalopathy with persistent coma, seizures, delayed language development, spastic quadriplegia, aphasia, and cortical blindness are seen as sequelae of submersion accidents. Unfortunately, despite a great deal of effort placed into trying to predict the ultimate neurologic outcome of drowning victims, it remains impossible to predict outcomes with accuracy for individual patients [26].

**Musculoskeletal Effects**

Children who develop anoxic encephalopathy because of drowning
frequently develop musculoskeletal problems [27]. These problems result from spasticity, which appears to be more aggressive in these children than in those with other forms of spastic disorder. The most common of these are lower extremity contractures, hip subluxation or dislocation, and scoliosis [27].

**Serum Electrolytes**

Experimental studies with animals reveal significant differences in serum electrolytes between freshwater and saltwater drowning [28]. In the clinical setting, swallowing large amounts of seawater over an extended period of repeated submersions has been reported to cause significant changes in serum sodium, potassium, chloride, and magnesium levels [29]. This happens rarely, however, and the body corrects most of the alterations that do occur. Therefore, the actual clinical impact of electrolyte changes is minimal.

**Hematologic Effects**

Patients presenting with drowning episodes rarely require medical intervention for anemia. Studies have demonstrated near-normal hemoglobin values in both seawater and freshwater [28]. In the best study of the affect of drowning on coagulation, overt disseminated intravascular coagulation was 13 times more likely in victims of cardiac arrest from drowning as opposed to nondrowning cardiac arrest victims [30]. The authors speculated that ischemia-induced tissue plasminogen activator release plays a role in this phenomenon.

**Renal Effects**

Acute tubular necrosis, hemoglobinuria, and albuminuria have all been reported as consequences of submersion accidents [31]. Diuresis has traditionally been considered to be a result of changes in renal tubular function as a result of hypothermia [32]. However, diuresis is seen in experimental submersions at any temperature [32]. Drowning victims also frequently present with metabolic acidosis as a result of lactate accumulation [33].

**Cardiac Effects**

Submersion in water causes an increase in left atrial diameter and a
decrease in heart rate [34]. Atrial fibrillation and sinus dysrhythmias are common but rarely require therapy. PR, QRS, and QT interval prolongations as well as J point elevation can be seen as in other causes of hypothermia [24]. The most common arrhythmias seen in cardiac arrests because of drowning are asystole followed by pulseless electrical activity [35].

The anoxia caused by drowning can also have an effect on hemodynamics. There may be transient increases in central venous and pulmonary artery occlusion pressures and a persistent decrease in cardiac output that may last more than 4 hours. These findings are independent of the tonicity of the solutions used and no different from those of anoxic controls.

Infectious Complications

Although a variety of infections are reported to be associated with drowning, pneumonia is the predominant infection described. Aspiration of mouth contents, gastric contents, and contaminated water all play a role in the development of pneumonia after drowning. A wide variety of organisms, including aerobic Gram-negative bacteria, aerobic Gram-positive bacteria, and fungi, have been described [36]. Combinations of infections, some with opportunistic organisms, have also been described [37]. Because organisms that can survive in very cold water usually cannot survive and proliferate at human body temperature, most pneumonia cases occur after warm-water drowning [37]. In addition to pneumonia, cases of brain abscess, meningoencephalitis, bacteremia, skin and soft tissue infections, and endophthalmitis are reported to occur.
DIAGNOSIS AND CLINICAL PRESENTATION

History
The minimum background historic information that must be obtained includes the patient’s age; underlying cardiac, respiratory, or neurologic diseases; and medications used. It is also important to determine the activities precipitating the submersion, such as boating, diving, or ingestion of drugs or alcohol; the duration of submersion; and the temperature and type of water in which it occurred.

Physical Examination
The initial physical examination is often hurried, with more detailed assessment delayed until resuscitative efforts have been established. Tachypnea is the most frequent finding, and tachycardia is also common. Patients may also be apneic and pulseless. Hypothermia is common and depends on the temperature of the water and duration of submersion. It is important that an appropriate thermometer be used that can accurately measure hypothermic temperatures because the duration of resuscitation may depend on this value. Other findings include fever and signs of pulmonary edema. Any physical findings seen in cases of cerebral anoxia or severe hypothermia may also be seen in drowning. In addition to revealing the consequences of hypoxia/anoxia and hypothermia, the major importance of the physical examination is to uncover coexisting injuries that may have caused or resulted from the submersion.

Various classification systems have been proposed for use with drowning victims. None of them are uniformly applied, and their value has yet to be proven in the clinical arena.

Laboratory Studies
Hemoglobin, hematocrit, and serum electrolytes are usually normal on arrival in the emergency department whether the submersion occurred in freshwater or saltwater [9]. Arterial blood gas analysis frequently shows metabolic acidosis and hypoxemia. The blood alcohol level, prothrombin time, partial thromboplastin time, serum creatinine, urinalysis, and drug screen should also be obtained to help determine the cause of the accident and assess for complications of drowning. Cervical spine films should be performed whenever there is evidence of trauma. An electrocardiogram should be obtained and continuous monitoring performed whenever there is a significant chance of dysrhythmia. Chest
radiographs frequently demonstrate some degree of pulmonary edema. Some films display confluent alveolar densities primarily in the perihilar regions, whereas others exhibit a diffuse, almost homogeneous nodular pattern bilaterally.
THERAPY

The treatment of nonfatal drowning should be approached in four phases.

Initial Resuscitation

Resuscitation of apneic or pulseless drowning victims should be initiated immediately and continue as needed throughout the prehospital phase into the emergency department. Mouth-to-mouth resuscitation may be begun in the water if the rescuer is a strong enough swimmer [39]. However, the rescuer must not put himself or herself in jeopardy. When performing rescue breathing, the rescuer should carefully support the victim’s neck to prevent exacerbation of undiagnosed vertebral injuries. Full CPR with chest compressions should begin immediately on arrival on shore and proceed according to standard guidelines, advanced life support should begin as soon as appropriate providers arrive and all victims requiring resuscitation should ultimately be transported to a hospital [40]. The use of the Heimlich maneuver in the absence of a foreign body obstruction was strongly recommended against by an Institute of Medicine Report [41].

Resuscitation must be continued for victims of cold-water submersion at least until the patient has been rewarmed. Core temperature should be obtained immediately on arrival at the emergency department and monitored carefully during the first several hours. All drowning victims with cardiopulmonary arrest and hypothermia should be rewarmed rapidly only to a temperature between 32°C and 34°C and then maintained at that level (see following discussion) [42]. In the field, wet clothing should be removed and passive external rewarthing plus inhalation of heated oxygen started. In the hospital, extracorporeal circulation should be used for cases of severe hypothermia from drowning, especially with circulatory collapse [43]. This method has the advantage of rapidly and directly rewarthing the core. It can also correct the metabolic acidosis that commonly occurs. When this technique is not possible, rewarthing with warmed peritoneal lavage, hemodialysis, or heated oxygen can be attempted (for an in-depth discussion of rewarthing techniques, see Chapter 184).

A more difficult question is when and how long to resuscitate victims of warm-water submersion. As previously mentioned, there is no clearly
established method of predicting ultimate neurologic recovery for individual patients. Therefore, until more information is available, the decision to terminate resuscitation must be based on a variety of factors particular to the individual case. On the other end of the clinical spectrum, victims who are asymptomatic and have normal oxygenation at 6 to 8 hours after presentation do not deteriorate during the subsequent 18 to 24 hours and do well in the long term [44,45].

**Therapy of the Underlying Cause**

If there is any question of possible head or neck trauma, the neck should be immobilized in a brace until cervical spine films are available. Hypoglycemia and severe electrolyte abnormalities can be detected on routine serum testing and corrected rapidly in the emergency department. Serum alcohol levels and a drug screen can detect potential intoxicants and prompt administration of necessary antidotes or other measures. Anticonvulsant levels can help tailor therapy for known epileptic patients.

**Treatment of Respiratory and Other Organ Failure**

The initial management of all pulmonary edema states involves monitoring PaO$_2$ and providing appropriate supplemental oxygen. Mechanical ventilation with positive end-expiratory pressure (PEEP) should be instituted if refractory hypoxic or hypercapnic respiratory failure develops. Excessive amounts of PEEP could adversely affect PaCO$_2$ and intracranial pressure and, therefore, have an adverse effect on cerebral perfusion. Moderate levels of PEEP used to enhance alveolar recruitment and enable adequate oxygenation are unlikely to have such an adverse impact. The standard of care for the management of ARDS from any cause is the use of low-tidal volume, low-pressure ventilation [46] (Table 171.1). Use of such a strategy has been shown to have a major effect on survival of ARDS patients. However, because of the potential impact of hypercapnia on cerebral blood volume, permissive hypercapnia should not be employed without intracranial pressure monitoring in comatose drowning victims [25].

ARDS, acute respiratory distress syndrome.

Other therapies for the respiratory complications of drowning have been proposed, but none of those has demonstrated improvements of outcomes. Examples of these types of therapies include exogenous surfactant in respiratory failure and prophylactic antibiotics. We do not advocate the use of either of these therapies.

Treatment of other end-organ damage must be approached systematically. Serum electrolytes rarely require therapy. The treatment of renal failure focuses on optimizing fluid status and renal blood flow. Severe cases may require temporary dialysis. Lactic acidosis should be corrected by restoration of adequate ventilation and circulation. The only clinically significant hematologic effect is disseminated intravascular coagulation (DIC). The management of DIC is addressed in Chapter 88.

The cardiac dysrhythmogenic effects of hypothermia are corrected by rewarming. Sinus and atrial dysrhythmias as well as most interval prolongations rarely require additional therapy. For a discussion of the treatment of hypothermia-related malignant ventricular dysrhythmias, see Chapter 184.

Musculoskeletal complications of nonfatal drowning are treated in standard fashion. Contractures are treated with casts or splints; subluxated or dislocated hips can be approached with appropriate operative procedures; and scoliosis is treated with bracing or spinal instrumentation [27]. The relative success of these interventions for this population is unclear.

**Neurologic Therapy**

The quality of the evidence supporting any intervention is poor when addressing neurologic resuscitation of the drowning victim. Therefore, much of what is recommended is based on a consensus understanding of the available information supplemented by general principles of resuscitation. The following recommendations are based on the World Congress on Drowning and more recent publications.
Restoration of spontaneous circulation is the highest priority goal. In-water rescue may be attempted by a trained lifeguard, but untrained individuals are likely to impair their own swimming by doing so and will probably be better served by bringing the victim to land. Because studies that established the efficacy of compression-alone CPR excluded drowning victims, and because the cause of drowning-related cardiac arrest is usually respiratory, conventional CPR with compressions and rescue breathing is recommended [25,47].

Core temperature should be monitored continuously. It is not necessary to continue aggressively rewarming a drowning victim once spontaneous circulation has been recovered, unless the hypothermia is thought to be contributing to ongoing arrhythmias or other serious pathology. Hyperthermia should be prevented and normothermia maintained at all times in the acute recovery period. Therapeutic hypothermia to a core temperature of 32°C to 36°C is recommended for a period of 24 hours for comatose survivors [48,49,50].

Seizures should be looked for and treated as necessary. The head of the bed should be elevated to 30 to 45 degrees while in the ICU. Blood glucose concentrations should be monitored and normoglycemia maintained. Hypoxemia and hypotension should be corrected. There is no pharmacologic therapy that has been shown to enhance brain recovery [25].
CONCLUSIONS

The course of nonfatal drowning is variable. Patients who receive prompt CPR, are rapidly restored to a perfusing rhythm, and regain neurologic function usually have dramatic and complete recoveries. On the other hand, patients with delayed resuscitation and those who do not rapidly recover neurologic function often have poor outcomes. Although freshwater and seawater drownings cause different clinical pictures in experimental animals, they are difficult to distinguish for human drowning victims. In general, patients who aspirate water present with hypoxemia and metabolic acidosis. They usually do not aspirate enough fluid to produce changes in blood volume, electrolytes, hemoglobin, and hematocrit of sufficient magnitude to be life-threatening.

The development of treatments specifically for drowning victims has been very slow. In general, most therapies are general treatments directed at cardiac arrest and ARDS. Treatment varies with the severity of the illness. For severely hypothermic patients, rewarming methods should be instituted immediately. These include removing wet clothing, covering with warm blankets, infusing warm fluids intravenously, and performing gastrointestinal irrigation with warm fluids. If the patient’s temperature is less than 32°C, core rewarming may be most easily accomplished by cardiopulmonary bypass or peritoneal dialysis with a potassium-free dialysate warmed to 54°C. The desired core temperature for patients after cardiac arrest is 32°C to 36°C. Therapy for patients with severe hypoxemia includes institution of all the supportive modalities used for ARDS in Chapter 163. Abnormalities of multiple organ systems must be addressed systematically. The most important methods for reducing deaths from drowning currently reside in the area of drowning prevention.
REFERENCES

Asthma is a chronic inflammatory disease of the airways characterized by variable airway obstruction [1]. Inflammation of the airways causes airway obstruction by making airway smooth muscle more sensitive to contractile stimuli, by thickening the airway wall with edema and inflammatory cell infiltration, by stimulating glands to secrete mucus into the airway lumen, by damaging the airway epithelium, and by remodeling the architecture of the airways.

Acute exacerbations of asthma may punctuate the course of mild, moderate, or severe cases of chronic asthma. These exacerbations or flares of asthma can be life-threatening and are characterized by an acute, progressive worsening of respiratory symptoms and pulmonary function that is severe enough to warrant a change in treatment [1]. Typically, mild-to-severe exacerbations are triggered by poor adherence to asthma controller medications or by exposure to environmental factors such as inhaled allergens, irritants, or viral infections of the respiratory tract. Assessment, management, and prevention of exacerbations of asthma, especially those leading to respiratory failure, are the critical challenges of caring for adult patients with asthma [1–3]. Severe exacerbations of asthma leading to critical illness are the main focus of this chapter.

**EPIDEMIOLOGY**

According to the most recent data by the Center for Disease Control, the prevalence of asthma in the United States is 7.3% [4]. Worldwide, clinical asthma ranks among the most common chronic diseases, with a prevalence ranging from 1.04% in Vietnam to 21.5% in Australia [5]. In general, asthma prevalence increases with urbanization and westernization of societies.

Asthma exacerbation rates vary by season with peaks in emergency room visits and hospitalizations coinciding with respiratory viral
infections, especially rhinoviral infections, in late summer and early autumn. In 2010 National Hospital Discharge Survey data, annual rates for inpatient hospital discharges for asthma in the United States were 18.3 per 10,000 population-age less than 18 years and 13 per 10,000 population-age 18 and over [4]. Although there remain important racial and gender differences in the rates of hospitalization, there was an overall decline in hospitalizations from 1995 to 2002, possibly due to better management and prevention [6].

In 2013, there were 3,630 deaths due to asthma in the United States indicating a death rate of 10.7 per million population of all ages [4]. Asthma mortality rates also have an annual cycle but do not strictly parallel the cycle for exacerbations. Among children, mortality peaks during the summer months, but, with increasing age, asthma mortality becomes more common during the winter months [7]. In 2013, the death rate for adults aged 18 years and older was 14.1 deaths per million population, but it is notable that there are large racial differences in the risk of death due to asthma. For all ages, non-Hispanic Blacks had a death rate of 25.9 per million population, while non-Hispanic Whites had a rate of only 8.4 per million population [4]. Deaths among patients hospitalized for asthma do account for one-third of asthma-related mortality, but potential differences of hospital care do not appear to account for racial disparities, and this suggests that prehospitalization factors are important [8].
PATHOPHYSIOLOGY

Pathology

Bronchial biopsy specimens from patients with asthma are pathologically abnormal [9–12], with collagen deposition beneath the epithelial basement membranes, mucosal infiltration by eosinophils and neutrophils, mast cell degranulation, and epithelial damage. These findings occur in both severe and mild asthma, suggesting that airway inflammation is of primary importance in the pathogenesis of asthma.

For exacerbations of asthma, the pathology of the airways is variable, reflecting at least two recognized clinical subtypes of exacerbation—slow onset and rapid onset. Slow onset exacerbations are the most common (approximately 80% of exacerbations) and the patient presents with more than 2 to 6 hours of symptoms—often days or weeks of symptoms [13–15]. This suggests that most such patients should have sufficient time to seek medical attention for worsening shortness of breath [16]. At autopsy, the lungs of patients who die of “slow-onset” asthma exacerbations are hyperinflated with thick tenacious mucus filling and obstructing the lumens of the airways. Microscopically, there is an eosinophilic bronchitis, with pronounced areas of mucosal edema and desquamation of the epithelium. Typically, hypertrophy and hyperplasia of smooth muscle are present and the muscle appears contracted [17].

The patient with the rapid-onset type of exacerbation presents with severe symptoms that have rapidly progressed over 2 to 6 hours [13–15]. These rapid-onset exacerbations may represent 8% to 14% of asthma exacerbations in general and can be fatal, leading to death in only a few hours after symptom onset [13,15]. Pathologically, airway obstruction by mucus is not prominent, and there is a neutrophilic, rather than eosinophilic, predominance of inflammatory cells in the airway submucosa [18]. There are no specific clinical characteristics that reliably predict which patients are prone to these rapid-onset asthma exacerbations. However, patients with rapid-onset asthma exacerbations may more commonly report sensitivity to nonsteroidal anti-inflammatory drugs [15].

Pathogenesis

Asthma is a disease or group of diseases with complex underlying genetics [19]. Why airway inflammation develops in the asthmatic patient is not understood entirely, but much evidence suggests an important role for Th2 cytokines [20]. Inhaled allergens, pollutants, smoke, and viral
infections all may play a role in augmenting the baseline airway inflammation present in the asthmatic airway [1,2,21]. When these environmental triggers interact with the asthmatic airway, the inflammation is intensified and the released mediators have potent effects on smooth muscle cell function, epithelium and microvascular integrity, neural function, and mucus gland secretion [22]. All these factors contribute to increased narrowing of the asthmatic airway with smooth muscle contraction, mucus secretion, epithelial cell sloughing into the lumen, and edema and inflammatory cell infiltration of the airway wall. The resulting acute increase of airway obstruction is commonly referred to as an acute exacerbation of asthma.

Physiology

The major physiologic consequences of airway obstruction are hypoxemia and increased work of breathing. Understanding these physiologic disturbances is important for management of severe exacerbations of asthma.

Narrowing the caliber of airway lumens causes hypoxemia by two mechanisms. First, increases in the resistance to flow in the conducting airways result in uneven distribution of ventilation to the alveoli. Hypoxic vasoconstriction of vessels that supply underventilated alveoli partially compensates for this uneven ventilation, but overall ventilation–perfusion (V / Q ) ratios remain abnormal and are the principal cause of hypoxemia during asthma exacerbations [23]. Consequently, even patients with severe exacerbations of asthma usually respond favorably to supplemental oxygen. A second, less common, cause of hypoxemia among asthmatics is right-to-left shunt due to atelectasis of lung distal to airways that are completely occluded by mucus or due to interatrial shunt precipitated by increased right atrial pressures from asthma-related increases of pulmonary vascular resistance [24,25].

The second physiologic consequence of severe airway obstruction is increased work of breathing. During acute exacerbations, respiratory muscles must expend increased energy, generating large changes of pleural pressure to overcome high airway resistance [26]. The resulting discordance between respiratory effort and the change in thoracic volume may play some role in the patient’s sensation of dyspnea and central drive to increase minute ventilation. The ensuing rapid respirations further increase the work of breathing and worsen air trapping behind narrowed airways that prematurely close during expiration. The dynamic hyperinflation of the lung itself leads to increased respiratory muscle
energy costs because it restricts vital capacity due to high thoracic volumes where alveolar dead space is increased, the respiratory muscles are at suboptimal mechanical advantage, and the lung is less compliant. All of these factors contribute to the significant increase of the work of breathing and the respiratory muscles must expend more energy to achieve the same alveolar ventilation. Initially, the respiratory muscles may be able to exert the force needed to maintain alveolar ventilation, but the muscles may fatigue if airway resistance increases rapidly, is sustained, or when there is inadequate oxygen delivery to these muscles [27,28]. Dynamic hyperinflation due to severe airway obstruction also may impair cardiac performance by increasing right ventricular afterload, decreasing venous return to the left atrium, and by causing diastolic dysfunction [3,25].
DIFFERENTIAL DIAGNOSIS

Not all wheezing is due to asthma (Table 172.1). Obstruction of the airway at any level can produce wheezing and dyspnea that can be confused with asthma. For example, vocal cord dysfunction syndrome [29] is an extrathoracic cause of episodic upper airway obstruction that can be confused with acute asthma. This diagnosis is suggested by the presence of stridor and wheeze in the absence of increased alveolar-arterial oxygen tension difference, extrathoracic variable obstruction on the flow-volume loop of pulmonary function tests, and by observing paradoxical closure of vocal cords during inspiration during laryngoscopy.

Furthermore, many disease processes other than asthma can obstruct the lower airways to produce wheezing and dyspnea (Table 172.1). Systemic anaphylaxis can cause wheezing and should be considered among the differential diagnoses especially when respiratory symptoms have been of rapid onset or progression [30]. A diagnosis of anaphylaxis is suggested by acute-onset wheezing, stridor, urticaria, nausea, diarrhea, and hypotension (especially after insect bites, drug administration, or intravenous contrast). Exacerbations of chronic obstructive pulmonary disease (COPD) present similarly to acute asthma, but chronic bronchitis or emphysema, or both, can usually be distinguished from asthma historically. However, consensus guidelines do recognize an asthma–COPD overlap syndrome that is characterized by chronic airflow obstruction and the presence of features that are associated with both asthma and COPD [1,31]. Pulmonary thromboembolism can masquerade as an exacerbation of asthma because the mediators released by platelets from thromboemboli sometimes cause bronchoconstriction and wheezing. However, hemoptyisis, pleuritic pain, and pleural effusions rarely are seen in acute exacerbations of asthma.

Pulmonary edema, either cardiogenic or non-cardiogenic, can obstruct small airways with mucosal swelling to produce acute wheezing. However, in these cases the clinical history, physical examination, and chest radiographic changes that show vascular redistribution of blood flow and alveolar filling help exclude asthma as the primary diagnosis. Notably, however, acute, reversible left ventricular dysfunction (e.g., takotsubo cardiomyopathy) has been described as a possible complication of severe exacerbations of asthma; the underlying mechanism for this is unclear, but it may be due to the acute effects of intensive treatment with β-adrenergic agonists [32]. Aspiration can present with acute dyspnea and wheezing. In this case, a history of impaired consciousness or inability to protect the airway suggests the
diagnosis and chest radiograph or ultrasound examination may show pulmonary infiltration.
ASSESSMENT

Failure of the physician to appreciate the severity of airway obstruction in acute asthma is not uncommon. The cornerstone of evaluation of patients with asthma exacerbations is the objective measurement of airflow. However, because some patients, especially those with severe exacerbations, may be unable to perform the necessary testing maneuvers, the physician also must be adept at recognizing certain historical features and physical findings that strongly suggest high risk for severe airway obstruction.

History

A history of baseline pulmonary function tests that show persistent decreases of the forced expired volume of air in 1 second (FEV$_1$), loss of lung elastic recoil, and hyperinflation at total lung capacity are associated with increased risk of near-fatal asthma [33]. A recent history of poorly controlled asthma (increases of dyspnea and wheezing, frequent nocturnal awakenings due to shortness of breath, increased use of β-adrenergic rescue medications, increased diurnal variability of peak expiratory flow, and recent hospitalizations or emergency department visits) and any history of a prior near-fatal asthma exacerbation (prior admission to an intensive care unit or intubation for asthma) are the most important predictors of a patient’s propensity for severe life-threatening asthma exacerbations [1,2,34–37]. Current or recent use of oral corticosteroids, not currently using inhaled corticosteroids, a history of psychosocial problems, poor adherence with asthma medications, and a history of food allergies are other warnings that the patient is at risk of asthma-related death [1,2]. Patient complaints of severe breathlessness or chest tightness or difficulty walking more than 100 feet (30.48 m) also suggest severe airway obstruction. Cigarette smoking also has been associated with higher in-hospital and posthospitalization mortality [38]. In general, patients are somewhat better judges of the severity of their airway obstruction during an attack of asthma than are physicians who elicit their history at the bedside [39]. However, the patient’s own assessment of airway obstruction should never be the exclusive means of assessing the severity of airway obstruction. Notably, patients with a history of severe asthma sometimes have a blunted perception of dyspnea [40,41]. When assessing risk for fatal asthma, other important historical details include identification of current medications and coexisting illnesses, such as psychiatric disease, that interfere with medical follow-up and cardiopulmonary disease. A history of known coronary artery
disease is important because the patient may be more sensitive to the stimulatory effects of $\beta_2$-adrenergic agonists and to the cardiac complications of hypoxemia. These patients may also be receiving $\beta_2$-adrenergic antagonists that are making control of their asthma worse.

**Physical Examination**

Physical examination is important for excluding other causes of dyspnea (see Differential Diagnosis section) and assessing the degree of airway obstruction. Tachycardia (greater than 120 beats per minute), tachypnea (greater than 30 breaths per minute), diaphoresis, bolt-upright posture in bed, pulsus paradoxus greater than 10 mm Hg, and accessory respiratory muscle use all should be regarded as signs of severe airway obstruction [42]. However, because the absence of these signs does not rule out severe obstruction, physical examination cannot be relied on exclusively to estimate the severity of airway obstruction. The amount of wheezing heard on auscultation of the chest is a notoriously poor method of assessing the severity of airway obstruction [43]. Cyanosis is a late, insensitive finding of severe hypoxemia. Abnormal thoracoabdominal motion (e.g., respiratory muscle alternans, abdominal paradox) and depressed mental status due to hypoxemia and hypercapnia are ominous indicators and can herald the necessity for emergent mechanical ventilation [44].

**Pulmonary Function Tests**

To evaluate a patient who is having an acute exacerbation of asthma, an objective measure of maximal expiratory airflow should be performed [1,2]. An exception to this is the patient who is unable to perform a testing maneuver due to a severe, life-threatening exacerbation with obvious airway compromise and cyanosis. Peak expiratory airflow rate (PEFR) and FEV$_1$ are equally acceptable bedside measures to quantify the degree of airway obstruction. These tests are valuable for the initial assessment and for assessing responses to therapy, especially after 1 hour of treatment [1]. In general, a pretreatment PEFR or FEV$_1$ of less than 50% of baseline (either the predicted value or the patient’s best-known value) indicates a severe exacerbation of asthma. Guidelines recommend reassessment of lung function one hour after initiation of treatment and then frequent reassessments thereafter (Table 172.2) [1,2,45].

#### Arterial Blood Gas Analysis

Analysis of arterial blood gases (ABGs) has a role in assessing and managing severe asthma exacerbations (see Chapter 27) and should be performed for suspected hypoventilation, severe respiratory distress, or when spirometric test results are less than 25% predicted [37]. Also, any patient who fails to respond to the first 30 to 60 minutes of intensive bronchodilator therapy should have an ABG analysis performed.

Although ABG values are not predictive of overall patient outcomes, there is some correlation between hypoxemia and hypercapnia and the degree of airway obstruction measured by FEV₁. A partial pressure of arterial oxygen (PaO₂) less than 60 mm Hg or a pulse oximeter oxygen saturation value less than 90% on room air should be regarded as additional evidence that the patient’s exacerbation is severe. Therefore, although ABG analysis is not recommended as routine during the initial evaluation of a patient with an acute exacerbation of asthma, it should be done for the evaluation of severe cases. One study did find that the frequency of ABG analysis in the initial evaluation of severe exacerbations decreased from 1997 to 2000 and that study suggested that ABG’s may be underutilized in the evaluation of severe exacerbations [46].

Understanding the expected changes of the partial pressure of arterial carbon dioxide (PaCO₂) during an asthma exacerbation is important for recognition of a rapidly deteriorating course. With modest airway obstruction, the patient’s mild dyspnea stimulates an increase in minute ventilation that meets or exceeds the level required to maintain normal alveolar ventilation. Thus, patients with modest obstruction have a
normal or slightly below normal PaCO₂. As airway obstruction worsens, dyspnea becomes more severe and the central nervous system drive to increase minute ventilation becomes intense. Typically, the increase in minute ventilation exceeds the level required to maintain constant alveolar ventilation; consequently, patients with moderate-to-severe obstruction have lower than normal PaCO₂ and an acute respiratory alkalosis. As the airway obstruction becomes more severe and prolonged, high minute ventilation can no longer be maintained by the respiratory musculature and alveolar ventilation decreases. As a result, the PaCO₂ rises toward normal and then continues to climb, resulting in hypercapnia and respiratory acidosis. Thus, a normal or high PaCO₂ (greater than 40 mm Hg) during a severe exacerbation of asthma is a potentially ominous finding, often signifying the impending need for mechanical ventilation. Any coexisting conditions (malnutrition, advanced age) or medications (sedatives) that weaken respiratory muscle function or depress respiratory drive should be expected to accelerate the onset of hypercapnic ventilatory failure during acute exacerbations of asthma.

**Other Laboratory Studies**

For acute exacerbations of asthma, routine chest radiographs reveal few abnormalities other than hyperinflation [47]. However, although not recommended for routine assessment, for severe exacerbations chest radiography can be helpful when there is clinical suspicion of other causes of dyspnea and wheezing (see Differential Diagnosis section) or complications of severe airway obstruction [37]. Chest radiographs should be examined for evidence of enlarged cardiac silhouette, upper lung zone redistribution of blood flow, pleural effusions, and alveolar or interstitial infiltrates because any one of these findings suggests a diagnosis other than or in addition to acute asthma. In addition, chest radiography allows the early detection of common complications of severe airway obstruction, including pneumothorax, pneumomediastinum, and atelectasis. Also, lung infiltrates on chest radiographs can be compatible with a diagnosis of asthma complicated by mucoid impactions (e.g., V or Y or cluster of grapes-shaped densities) and/or complications associated with them (e.g., lobar collapse), allergic bronchopulmonary aspergillosis or eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome).

Among the elderly, for patients with severe hypoxemia, and for individuals with suspected cardiac ischemia or arrhythmias, an electrocardiogram should be performed. Sinus tachycardia is common during acute exacerbations of asthma, but less common and transient
findings include right-axis deviation, right ventricular hypertrophy and strain, P pulmonale, ST- and T-wave abnormalities, right bundle-branch block, and ventricular ectopic beats [48].
THERAPEUTIC AGENTS

Optimal management of an acute exacerbation of asthma begins with a careful assessment of the degree of airway obstruction. This initial assessment and repeated objective measures of airway obstruction guide treatment that combines supportive measures, bronchodilator therapy, and anti-inflammatory therapy (Table 172.3).

**TABLE 172.3 Treatment of Severe Acute Exacerbations of Asthma**

Pharmacologic agents

Anti-inflammatory agents
- Systemic corticosteroids (oral preferred unless impaired intestinal absorption)

Bronchodilators
- Inhaled, short-acting β₂-adrenergic agonists
- Inhaled, short-acting cholinergic antagonists

Intravenous MgSO₄ (not routine; consider in severe, refractory cases)

Oral or intravenous methylxanthines (not routine or recommended)

Systemic β₂-adrenergic agonists (not routine or recommended)

General anesthetics (not routine)

Supportive measures
- Frequent reassessment
- Supplemental oxygen
- Fluid management
- Invasive mechanical ventilation if needed (controlled hypoventilation)

Helium–oxygen mixtures to drive nebulizer (not routine; consider in severe, refractory cases)

Lavage by bronchoscopy (not routine, intubated patients only)

Education
Avoidance of asthma triggers
Medication use
Access to medical follow-up
Home monitoring of airway obstruction

Because the dominant causes of airway obstruction during an acute exacerbation of asthma are the result of airway inflammation, the cornerstone of treatment is anti-inflammatory therapy with systemic corticosteroids, administered within 1 hour of presentation [49]. Because corticosteroids take at least 4 to 6 hours to begin to have a beneficial effect and many of the inflammatory causes of airway obstruction may take days to resolve, the medical challenge is to support patients until the inflammatory processes have responded to corticosteroids.

$\beta_2$-Adrenergic agonists relieve airway obstruction due to airway smooth muscle contraction, and this is an important therapeutic maneuver during initial treatment. Although these bronchodilators relieve only one component of the airway obstruction during severe exacerbations of asthma, even small improvements of airflow can lead to important clinical benefits in the acute setting. Of the available bronchodilators, $\beta_2$-adrenergic agonists are the most effective and rapidly acting and, therefore, most useful during that critical time before the onset of corticosteroid action [50]. Other measures that support the patient until the inflammatory processes in the airways have resolved include supplemental oxygen, judicious fluid administration, and, when indicated, mechanical ventilation.

$\beta_2$-Adrenergic Agonists

$\beta_2$-Adrenergic agonists bind to $\beta_2$-adrenergic receptors on airway smooth muscle cells and cause relaxation of the muscle cell [51]. Although the primary cellular target of $\beta_2$-adrenergic agonists is airway smooth muscle, other cell types in the airways also express $\beta_2$-adrenergic receptors that may regulate mediator release by mast cells, epithelial cells, and nerves. There are three general classes of $\beta_2$-adrenergic agonists [52]. First, short-acting $\beta_2$-adrenergic agonists (SABA) have bronchodilatory effects that last for 3 to 5 hours. They include epinephrine, isoproterenol, terbutaline, metaproterenol, albuterol, and fenoterol. These short-acting agents are rapidly acting with an onset of action less than 5 minutes and are the mainstay of bronchodilator therapy for acute asthma, especially albuterol [1,2]. Second, there are the long-acting $\beta_2$-adrenergic agonists (LABA) that have either slowly or
rapidly acting bronchodilatory effects lasting for at least 12 hours. Third, there are the ultra long-acting $\beta_2$-adrenergic agonists (ultra-LABA) that have half-lives suitable for once-daily dosing. Neither LABA nor ultra-LABA is currently recommended for the treatment of acute asthma exacerbations [1].

Among SABA medications, a single-isomer preparation (i.e., R-albuterol or levalbuterol) for inhalation is available. The potential advantage of this preparation is that the S-enantiomer present in racemic albuterol does not contribute to bronchodilation and might have deleterious effects on the airways. However, there have not been large, randomized, double-blind, and controlled trials in adults to show that this theoretical concern is clinically important. Moreover, a systematic review and meta-analysis of smaller studies concluded that levalbuterol was not superior to albuterol with respect to either efficacy or safety in the treatment of acute asthma exacerbations [53].

The major side effects of $\beta_2$-adrenergic agonists during the treatment of severe asthma exacerbations are tremor, cardiac stimulation, hypokalemia, and hyperlactatemia [52,54]. These side effects are potentially serious, especially in the elderly, who frequently have underlying cardiac disease. Cardiac toxicity can be minimized by using agonists with high $\beta_2$-adrenergic receptor selectivity, by avoiding systemic administration of $\beta_2$-adrenergic agonists, and by maintaining adequate oxygenation [55].

$\beta_2$-Adrenergic agonists can be administered to patients by inhalational, subcutaneous, or intravenous routes. Numerous studies have shown that the bronchodilator effects of inhaled $\beta_2$-adrenergic agonists are rapid in onset and equal to the effect achieved by systemic delivery [56]. Because the inhaled route allows administration of comparatively small doses directly to the airways with minimal systemic toxicity, this route is almost always preferable to systemic delivery [1,2].

Several options exist for the delivery of inhaled $\beta_2$-adrenergic agonists (see Chapter 169). A small-volume nebulizer is widely used. However, studies have shown that metered-dose inhalers (MDIs) equipped with spacer devices are as effective as small-volume nebulizers in the treatment of acute asthma, although some patients may have difficulty coordinating MDI use, especially during an acute exacerbation with severe respiratory distress [1,2,57,58]. Frequent, multiple inhalations of the medication may allow for progressively deeper penetration of the
drug into peripheral airways. In fact, continuous administration by nebulizer may be more effective for severely obstructed patients [59,60]. For administration of inhaled albuterol in the treatment of severe exacerbations of asthma, National Institutes of Health guidelines recommend treatment with MDI (90 μg per puff; four to eight puffs every 20 minutes up to 4 hours, then every 1 to 4 hours as needed) or nebulizer treatments, either intermittent (2.5 to 5.0 mg every 20 minutes for three doses, then every 1 to 4 hours as needed) or continuous (10 to 15 mg per hour) [2] (see Management section).

Because of its lower density than oxygen, helium–oxygen (heliox)–powered nebulizer treatments have the potential to improve penetration of aerosols into the lungs. However, a systematic review with meta-analysis comparing heliox versus air–oxygen driven nebulization found no support for helium-powered nebulization in the routine care of acute exacerbations of asthma [61]. However, the method may be considered for patients not responding to standard therapies [1].

Theoretically, systemic administration of β-adrenergic agonists could deliver drugs via the bloodstream to obstructed airways that are poorly accessible to inhaled aerosols. However, this theoretical advantage has not been supported by most studies. Subcutaneous epinephrine (adults, 0.3 mL of a 1 to 1,000 solution every 20 minutes for three doses) was a traditional therapy for acute asthma in emergency departments, but it is not more effective than aerosol delivery of β₂-adrenergic agonists [1,2]. A major concern with the use of subcutaneous epinephrine to adults has been cardiac toxicity. More selective β₂-adrenergic agonists, such as terbutaline, are available for subcutaneous use, but cardiac toxicity among elderly individuals is still a significant concern even with these more selective agents. Formerly, intravenous isoproterenol (0.05 to 1.50 μg/kg/minute) was formerly used to treat severe exacerbations of asthma. However, intravenous delivery of β₂-adrenergic agonists is no longer recommended for the routine treatment of even severe exacerbations of asthma [1,2]. No convincing evidence has shown intravenous administration to be superior to inhaled delivery of β₂-adrenergic agonists [56,62]. Both the lack of enhanced efficacy and the potential cardiac toxicity of intravenous β₂-adrenergic agonists have led most authorities to reserve intravenous delivery for those rare adult patients, closely monitored, who continue to deteriorate on mechanical ventilation despite maximal routine therapy with inhaled β₂-adrenergic agonists. It is important to emphasize again that intravenous β₂-adrenergic agonists are not recommended in guidelines and are unlikely to be any more effective than inhaled β₂-adrenergic agonists such as albuterol [1,2].
Cholinergic Antagonists

For asthma, the muscarinic cholinergic antagonists (e.g., atropine, ipratropium, and tiotropium) are less effective and more slowly acting bronchodilators than β₂-adrenergic agonists [52,63,64]. In general, these agents should not be used as the sole bronchodilator therapy for acute asthma. Exceptions may be bronchospasm induced by acetylcholinesterase inhibitors or β₂-adrenergic antagonists and patients with severe cardiac disease who are unable to tolerate β₂-adrenergic agonists.

However, inhaled cholinergic antagonists have a low incidence of side effects and are a recommended adjunct to β₂-adrenergic agonists for the initial treatment of severe exacerbations of asthma [1,2,65,66]. Because even small improvements of airway caliber could prove clinically significant for the severely obstructed and deteriorating patient, it is recommended that ipratropium be routinely added to β₂-adrenergic agonist therapy during the initial treatment of severe asthma exacerbations in the emergency department [1] (see Management section). However, inhaled ipratropium bromide currently is not recommended for routine use once a patient is hospitalized with a severe exacerbation of asthma [1,2]. The long-acting anticholinergic, tiotropium, has a role in treating outpatients with difficult to control asthma, but it does not have any established role for treating hospitalized patients with acute exacerbations of asthma [1,2,67].

Methylxanthines

Because the literature does not demonstrate a benefit to adding methylxanthines to β₂-adrenergic agonists in the acute setting and because they increase toxicity, methylxanthines are no longer recommended for the treatment of asthma exacerbations [1,2,68–70].

For the rare, critically ill patient whose condition is acutely deteriorating despite maximal recommended therapy with bronchodilators, corticosteroids, and other adjuncts [1,2], the use of methylxanthines might be considered by some physicians, although data are not supportive [71]. For patients not already taking methylxanthines, a loading dose of aminophylline (6 mg/kg lean body weight) can be administered over 20 to 30 minutes, followed by an intravenous infusion at the rate of 0.6 mg/kg/h. This infusion rate should be decreased when conditions are present that decrease methylxanthine clearance, especially congestive heart failure, cirrhosis, and the use of drugs such as cimetidine, ranitidine, allopurinol, oral contraceptives, erythromycin, ciprofloxacin, or norfloxacin. Six hours after initiation of the infusion, the
serum theophylline level should be checked and the infusion rate adjusted accordingly, with 10 to 15 μg/mL being therapeutic. Serum concentrations greater than 20 μg/mL are toxic.

Corticosteroids

Numerous studies have documented the safety and effectiveness of short courses of corticosteroids for the treatment of acute exacerbations of asthma [1,72–74]. Their beneficial effects are attributed to their many potent anti-inflammatory effects on multiple cell types [72,75].

Systemic corticosteroids are the principal therapy for acute exacerbations of asthma [1,2]. Prednisone, prednisolone, and methylprednisolone are the preferred agents. Compared with betamethasone and dexamethasone, neither prednisone nor methylprednisolone contain metabisulfites, and both have shorter half-lives. Although hydrocortisone has the shortest half-life, it has greater mineralocorticoid effect and may cause idiosyncratic bronchospasm in some aspirin-sensitive individuals [76].

The optimal route of corticosteroid administration (i.e., oral vs. intravenous) during the treatment of acute asthma is not well established by double-blind, placebo-controlled clinical studies. For initial treatment of an acute exacerbation of asthma, studies suggest that oral administration of corticosteroids is as effective as intravenous therapy [1,2,77,78]. Therefore, the oral route is preferred unless there is the possibility of impaired gastrointestinal tract transit time or absorption.

Inhaled corticosteroids do not have a well-established role for the treatment of acute exacerbations of asthma of hospitalized patients. However, in the Emergency Department setting inhaled, high-dose corticosteroids decrease hospitalization rates for patients not receiving systemic corticosteroids, but their benefit for patients receiving additional, systemic corticosteroids is not established [1,79].

The optimum dosages of corticosteroids for the treatment of acute asthma are also not well established by randomized controlled clinical trials [1,2,80]. One study compared 15, 40, and 125 mg methylprednisolone every 6 hours and suggested that patients improved most rapidly with the 125 mg dose [81]. However, most studies have failed to show a dose–response relationship for doses this high [80]. For example, one study showed no difference between 100 and 500 mg methylprednisolone for the emergency department treatment of asthma [82].

For adults, 2007 NIH guidelines recommend that prednisone,
methylprednisolone, or prednisolone all be given at 40 to 80 mg per day in one or two divided doses until PEFR is 70% of predicted or personal best [2]. The Global Initiative for Asthma (GINA) guidelines updated in 2015 describe appropriate dosing as the equivalent of 50 mg of prednisone as a single daily dose or the equivalent of 200 mg of hydrocortisone in divided doses as being adequate in most cases [1]. According to NIH guidelines the duration of systemic corticosteroid treatment for a patient requiring an emergency department visit or a hospitalization is usually 3 to 10 days [2]. GINA guidelines recommend a 5- to 7-day course for adults [1,83,84]. For courses of treatment lasting less than 1 week and for courses lasting up to 10 days, there is no established benefit to slowly tapering the daily oral corticosteroid dose, especially when the patient is also using inhaled corticosteroids [1].

Oxygen

Supplemental oxygen therapy should be the initial intervention in the emergency department [1,2]. Because ventilation–perfusion mismatch is the dominant cause of hypoxemia with asthma, the PaO₂ usually increases readily in response to low levels (2 to 4 L per minute oxygen by nasal prongs) of supplemental oxygen therapy. Studies have shown that titrated, low-flow oxygen therapy to achieve oxygen saturations of 93% to 95% is associated with better outcomes than the routine use of untitrated, high flow, 100% oxygen therapy [85,86]. In addition to mitigating the cardiac and neurologic complications of severe hypoxemia, low-flow supplemental oxygen minimizes potential episodes of hypoxemia due to the acute administration of β₂-adrenergic agonists, decreases elevated pulmonary vascular pressures due to hypoxic vasoconstriction, decreases bronchospasm due to hypoxia, and improves oxygen delivery to respiratory muscles.

Fluids

No convincing evidence has shown that fluid administration in excess of euvolemia hastens mobilization of inspissated secretions from the airways. Fluid therapy should be used conservatively unless significant dehydration is present.

Other Agents

Intravenous magnesium sulfate (for adults, 2 g MgSO₄ in 50 mL saline during 20 minutes) has bronchodilator properties. Magnesium sulfate is not recommended for routine use of the treatment of asthma exacerbations, but it may be considered for the treatment of the most
severe asthma exacerbations (FEV₁<25% to 30% or hypoxemia refractory to initial treatment) [1]. Additional study is needed, but some evidence suggests that its use may reduce hospitalization rates for the most severely obstructed patients who have an FEV₁ less than 25% of predicted [87]. Although the data are mixed, inhaled, rather than intravenous, magnesium sulfate may also have a role in the treatment of acute asthma. That is, for severe asthma exacerbations, albuterol nebulized diluted in magnesium sulfate solution may be a more effective bronchodilator than albuterol nebulized in normal saline [88,89].

Because of its lower gas density, some improvement in airway resistance may be achieved by delivering a mixture of helium and oxygen gases to patients with airway obstruction. However, guidelines do not recommend the routine use of heliox for the treatment of asthma and suggest that it be considered only for rare, severe cases unresponsive to standard therapies [1,2].

Some therapeutic agents that are used for the treatment of stable asthma have no established role in the treatment of severe exacerbations of asthma among hospitalized patients. These include aerosolized corticosteroids and sodium cromolyn as well as oral β₂-adrenergic agonists that may cause significant systemic toxicities. Although there is as yet no established role for the use of leukotriene antagonists for the treatment of acute asthma exacerbations, some evidence suggests a possible role and need for further study [90,91]. Mucus is an important cause of airway obstruction during acute exacerbations of asthma, but the routine use of mucolytics, such as acetylcysteine, potassium iodide, or human recombinant deoxyribonuclease (DNase), has not been shown to be effective for treating severe exacerbations of asthma, and at least one of these agents, acetylcysteine, may worsen cough and bronchospasm [92]. However, it is notable that acetylcysteine and DNase may be helpful during therapeutic bronchoscopy (see Additional and Unconventional Management Measures section).

Bacterial infections appear to play, at most, a minor role in the precipitation of severe asthma exacerbations [1,2]; for this reason, antibiotics are not routinely administered unless an active bacterial infectious process, particularly pneumonia or bacterial sinusitis, is suspected. However, intriguing evidence suggests that infections due to Chlamydia pneumoniae might play a role in the pathogenesis of asthma exacerbations for some patients [93].

Unless a patient is mechanically ventilated, sedation has no role in the
treatment of severe exacerbations of asthma [1,2]. Opioids and other sedating medications may depress the respiratory central drive to breathe that is critical for adequate minute ventilation. Theoretically, some opioids also may cause mast cell degranulation and worsen bronchospasm.
MANAGEMENT

Emergency Department

The National Asthma Education and Prevention Program and GINA have published and updated guidelines for the assessment and management of patients with asthma and these guidelines include the treatment of acute exacerbations [1,2]. These guidelines have been widely accepted, and we recommend them. Initial management of a patient with an acute exacerbation of asthma is based on the physician’s assessment of the degree of airway obstruction and the patient’s response to initial bronchodilator therapy using $\beta_2$-adrenergic agonists. If, during the initial assessment, the patient is in extreme distress and has evidence of fatigue, impaired consciousness, or hypercapnia such that respiratory arrest is judged imminent, endotracheal intubation and mechanical ventilation should be the first priorities and then systemic corticosteroids and nebulized $\beta_2$-adrenergic agonists and ipratropium should be started immediately. On the other hand, when respiratory arrest is not impending within minutes, 2 to 4 L per minute of supplemental oxygen should be initiated to keep oxygen saturation 93% to 95%; $\beta_2$-adrenergic agonists should be delivered by aerosol for three doses over 60 to 90 minutes (e.g., albuterol, 2.5 to 5.0 mg, every 20 minutes by small-volume nebulizer, then 2.5 to 10 mg every 1 to 4 hours as needed, or 10 to 15 mg per hour continuously or, alternatively, albuterol, 90 $\mu$g per puff, four to eight puffs by MDI with spacer every 20 minutes up to 4 hours, then every 1 to 4 hours as needed). When the PEFR is less than 50% of the predicted value, an oral (preferred) or intravenous systemic corticosteroid should be started immediately (e.g., prednisone 1 mg/kg/d up to 50 mg maximum or equivalent) and an inhaled anticholinergic as well (e.g., ipratropium bromide, 0.5 mg by nebulizer). After these treatments are initiated, a more detailed history and physical and laboratory examination can be completed. Close monitoring and repeated airflow measurements are critical for detecting further deterioration during this initial period of treatment.

After the initial treatment with a bronchodilator, patients are reassessed. Those who do not respond substantially (FEV$_1$ or PEFR greater than 60% of predicted) within 1 hour to initial treatment with $\beta_2$-adrenergic agonists should be given systemic corticosteroids (if not already given). Oral prednisone is generally recommended unless there is concern that gastrointestinal tract absorption will be less than optimal [1,2].
In addition to corticosteroids, treatment with β₂-adrenergic agonists and inhaled anticholinergics is continued for 1 to 3 hours with frequent reassessment. Patients who achieve an FEV₁ or PEFR of greater than 60% during this 1- to 3-hour period should be observed for at least 1 additional hour to ensure stability of the improvement. In one study, two-thirds of patients who presented to the emergency department responded to albuterol, with the FEV₁ increasing to at least 60% of predicted [94].

Many patients with such a good response do not require hospitalization. Exceptions are patients with a history that is suggestive of high risk for mortality from asthma (e.g., history of intubation and mechanical ventilation; Table 172.4). Patients discharged from the emergency department should be continued on systemic corticosteroids and β₂-adrenergic agonists, considered for initiation of inhaled corticosteroids, given instructions regarding medication use, given an action plan in case symptoms worsen, and given specific instructions for medical follow-up [1,2,67,95,96].

Patients who have an FEV₁ or PEFR that is greater than 40% but less than 60% after 4 hours of treatment have an incomplete response and
require a careful triage decision. Some patients do well when discharged with detailed instructions, close medical follow-up, and continued systemic corticosteroids. However, other patients do poorly if discharged. It has been recommended that patients with incomplete responses be hospitalized when there is any clinical feature to suggest high risk for asthma mortality (Table 172.4). Patients with an FEV\textsubscript{1} or PEF of less than 40% of predicted after 4 hours of intensive bronchodilator therapy (poor response) should be hospitalized, often in an intensive care unit (ICU) setting.

**Treatment During Pregnancy**

Pregnancy should not alter treatment of an acute exacerbation of asthma. Because severe asthma exacerbations have been associated with increased perinatal mortality, probably due to maternal hypoxia and respiratory alkalosis, the excellent control of asthma should be a main priority [97] (see Chapter 164). However, unfortunately, many pregnant women are suboptimally treated for asthma in the acute setting [98]. This is unfortunate because, in both the chronic and the acute setting, abundant evidence supports the safety of $\beta_2$-adrenergic agonist use during pregnancy [99]. Also, although chronic administration of systemic corticosteroids throughout pregnancy appears to carry some risk to the fetus, short courses of corticosteroids are considered safe for the fetus compared with the serious risks associated with poorly controlled asthma. Therefore, corticosteroids should not be withheld from pregnant women, who present with an acute asthma exacerbation. Treatment of chronic asthma during pregnancy should include inhaled corticosteroids [100], which is important for preventing development of acute asthma exacerbations [101].

**Routine Inpatient Management**

Most patients with severe exacerbations of asthma, who are admitted to the hospital, can be monitored and managed safely on a hospital ward that is well staffed by physicians, experienced nursing personnel, and respiratory therapists. However, patients with severe airway obstruction who are at high risk for mortality from asthma, especially those with an elevated PaCO\textsubscript{2} (greater than 42 mm Hg) or changes of mental status despite initial intensive bronchodilator therapy, need the close monitoring of an ICU setting for possible intubation and mechanical
ventilation.

Pharmacotherapy for hospitalized patients includes a continuation of the inhaled $\beta_2$-adrenergic agonists and systemic corticosteroids begun in the emergency department [1,2]. Specifically, it is not recommended that ipratropium bromide be routinely continued once a patient is hospitalized [1]. For patients with severe airway obstruction and only transient relief from treatment, inhaled $\beta_2$-adrenergic agonists can be administered frequently as needed (e.g., every 20 minutes). For patients with less severe obstruction or those with intolerable side effects, frequency can be reduced accordingly. Most patients require $\beta_2$-adrenergic agonists a minimum of every 4 hours; however, a study has shown that ad libitum administration of albuterol every 4 hours is as effective as regularly timed administration of albuterol [102]. Evidence indicates that delivery of $\beta_2$-adrenergic agonists by small-volume nebulizer and delivery by MDI with spacer give equivalent results [1,2,71].

Most hospitalized patients begin to show improvement in expiratory airflow after 6 to 12 hours of systemic corticosteroid therapy, but improvement sufficient for hospital discharge frequently takes 2 to 7 days. In one series, mean length of hospital stay was 4 days, with a range of 0.5 to 17.0 days [103]. Expiratory airflow should be followed to assess the patient’s progress. Patient exercise tolerance and PEFR usually improve incrementally during hospitalization, but it is common for patients recovering from exacerbations to have a hospital course punctuated by periods of worsening dyspnea, especially at night. These episodes of nocturnal worsening require patient assessment but generally respond well to inhaled $\beta_2$-adrenergic agonists. When the expiratory flow rate does not improve during the initial days of hospitalization, additional or alternative diagnoses, especially laryngeal dysfunction, congestive heart failure, and pulmonary thromboembolism, as well as gastroesophageal reflux disease and sinusitis, should be considered.

As the hospitalized patient recovers, the intensity of therapy is decreased gradually. When the patient has minimal or no wheezing, is no longer awakened by dyspnea at night, can tolerate activity without oxygen desaturation of hemoglobin, and has expiratory flow rates that have substantially improved, he or she is ready for hospital discharge. Patients generally should have a PEFR at least 70% of baseline at the time of discharge. Other patients with an incomplete response to therapy (50% to 70% of baseline) should be assessed individually.

Discharge planning is important for preventing future exacerbations (Table 172.5) [1,2]. Patients must be educated about asthma and the importance of seeking medical advice early in the course of exacerbations. Particularly important are detailed instructions on MDI use, routine measurement of PEFR, and keeping a symptom diary at
home. On discharge, the patient is given medication instructions with particular attention to oral and inhaled corticosteroids (see Corticosteroids section). This is important because bronchial hyperresponsiveness remains high for at least 10 days after discharge from an ICU for severe asthma [104]. Patients who have recovered from an exacerbation of asthma should be instructed to use short-acting inhaled $\beta_2$-adrenergic agonists on an as-needed basis only.

MANAGEMENT OF SEVERE RESPIRATORY FAILURE

Assessment

When acute hypoxemic or hypercapnic respiratory failure is severe, mechanical ventilation is potentially life-saving. Patients with severe obstruction can be supported with mechanical ventilation for the vital hours needed for corticosteroid action. However, mechanical ventilation for a severe asthma exacerbation can be complicated by morbidity and mortality, with associated mortality ranging from 0% to 38% in the literature [105–107].

The decision to initiate mechanical ventilation for a severe asthma exacerbation should be based on a number of considerations individualized for each patient [107]. For patients with severe distress for whom respiratory arrest has already occurred or is imminent, the need for intubation and mechanical ventilation is self-evident. The possibility of pneumothorax should be promptly addressed for these patients. Patients who are not in extremis should be monitored closely during initial bronchodilator therapy, and the physician should be prepared to perform intubation in case of substantial deterioration. The decision to intubate during a severe asthma exacerbation is a clinical judgment. For severely obstructed patients with decreasing objective measures of airflow, worsening mental status, or signs of respiratory muscle fatigue despite bronchodilator therapy, urgent intubation and mechanical ventilation should be strongly considered. In general, any patient who responds poorly to initial bronchodilator therapy and has an initial PaCO₂ of 40 mm Hg or more in association with moderately severe hypoxemia should have close serial clinical assessment and ABG monitoring. For patients with a PaCO₂ of greater than 55 to 70 mm Hg, increasing PaCO₂ (greater than 5 mm Hg per hour) in association with a PaO₂ of less than 60 mm Hg or the presence of metabolic acidosis, intubation, and mechanical ventilation should be very strongly considered. However, it is emphasized that when clinical signs indicate a need for intubation, the decision to intubate should be made immediately and never delayed, waiting for an ABG result. The role of noninvasive positive-pressure ventilation when managing patients with acute asthma is not established and guidelines do not make recommendations on its application, but they do emphasize close monitoring and avoidance of sedation if noninvasive mechanical ventilation is attempted [1,2,108] (see
Endotracheal Intubation

Airway control should be established by the most experienced personnel available because even minor manipulation of the larynx and trachea can precipitate vagal reflexes that elicit laryngospasm and bronchospasm. Atropine can be given before intubation to attenuate these vagally mediated reflexes. Lidocaine can be used to achieve topical anesthesia of the hypopharynx and larynx, but even lidocaine has been associated with bronchospasm [109]. Administration of a short- and rapid-acting intravenous benzodiazepine often can facilitate patient relaxation and preoxygenation, allowing time for a controlled intubation that minimally irritates the larynx and trachea. Opiates are not used for intubation or sedation in asthmatic patients because some narcotics can provoke nausea and vomiting and theoretically can provoke histamine release that worsens bronchospasm.

Oral, rather than nasal, intubation is preferred for patients with a severe asthma exacerbation because nasal polyps and sinusitis are common in asthma and because the oral route allows placement of a larger endotracheal tube (internal diameter, 8 mm).

Invasive Mechanical Ventilation

The guiding principle for mechanical ventilation during a severe exacerbation of asthma is to provide adequate oxygenation while minimizing the risk of barotrauma (Table 172.6). Because the risk of barotrauma is related to dynamic hyperinflation of the lungs and high plateau airway pressures, a ventilatory strategy that minimizes lung volumes and airway pressures should be used [1,2,107]. (See Chapter 166 for a discussion of initiating mechanical ventilation.)

</tbody>
</table>
With outmoded mechanical ventilation strategies that aimed to normalize the PaCO$_2$, the required high tidal volumes and rapid frequencies of ventilation promoted increased air trapping and high airway pressures. Most authorities now believe that high airway pressures are to be avoided because they are a major cause of serious morbidity and mortality during mechanical ventilation of asthmatic patients [107,110–116].

The modern strategy for mechanical ventilation for a severe exacerbation of asthma is controlled hypoventilation with permissive hypercapnia [1,2,107,110–116] (see Chapter 166). This strategy seeks to mitigate gas trapping and dynamic hyperinflation and does not attempt to establish a normal PaCO$_2$ as long as the minute ventilation and fraction of inspired oxygen maintain adequate tissue oxygenation. Physician acceptance of hypercapnia in this setting is termed permissive hypercapnia [110–112]. Gas trapping and dynamic hyperinflation can be monitored, indirectly, by following plateau airway pressures, the level of intrinsic positive end expiratory pressure (PEEP) or auto-PEEP, and flow versus time graphics on the ventilator [115,116]. However, the most well-studied correlate of gas trapping and dynamic hyperinflation during mechanical ventilation for severe asthma is the volume of gas that remains in the lungs at end inspiration [114–116] (see Chapter 166). When the volume of air at end inspiration above functional residual capacity (VEI) exceeds 20 mL per kg, there is increased risk of hypotension and barotrauma. However, it should be noted that measurement of VEI requires the use of paralytics.

Although the use of sodium bicarbonate to treat acidosis is controversial, advocates for its use in severe acute respiratory acidosis have regarded a pH of 7.20 to be the minimum safe level [117]. This impression and the practice of infusing sodium bicarbonate to maintain a pH of more than 7.20 is based on two uncontrolled studies in which stuporous and comatose patients with acute respiratory acidosis markedly and quickly improved when infusion of sodium bicarbonate increased the pH to greater than 7.20 [118,119]. However, no controlled studies of respiratory acidosis support the use of sodium bicarbonate to maintain a specific pH value.

The physiologic responses to metabolic and respiratory acidosis include increases in cardiac output, pulmonary arterial pressure, and heart rate, whereas systemic vascular resistance decreases and mean systemic arterial pressure remains unchanged [120–122]. In diseased
lungs, PaO$_2$ improves [120]. The hemodynamic changes are mediated directly by endogenous secretion of catecholamines, primarily norepinephrine, stimulated by decreases in pH. The effects of sodium bicarbonate infusions on these hemodynamic responses and gas exchange have been studied. As the acidosis lessens, cardiac output and PaO$_2$ worsen [121,122]. Moreover, sodium bicarbonate infusions have been shown neither to improve survival nor to enhance bronchodilation. Although studies from the 1950s and 1960s suggested that endogenous epinephrine release was depressed in acidosis, more recent studies have conclusively shown that it is either unchanged or augmented [122]. Because carbon dioxide is generated when infused sodium bicarbonate buffers hydrogen ions, infusion of sodium bicarbonate predictably raises carbon dioxide tensions in blood [123]. Because carbon dioxide readily diffuses across cell membranes, sodium bicarbonate therapy may cause paradoxic intracellular acidosis [124], and this may adversely affect survival. For these reasons, we suggest use of sodium bicarbonate only when the acidosis appears to be adversely affecting the patient’s hemodynamic status.

In managing patients during mechanical controlled hypoventilation with permissive hypercapnia, the minimum safe pH is not known. In three uncontrolled studies, pH values were not maintained at greater than 7.2, and outcomes did not appear to be adversely affected. Sodium bicarbonate was not given in one study unless pH was less than 7.15 [114]; in the other two studies, it was not given to any patient even when pH was 7.02 and less than 7.00 [110,125].

Neuromuscular blocking agents, such as pancuronium, vecuronium, and atracurium, can be used to help maintain low airway pressures during delivery of mechanical ventilation (see Chapter 4). Paralyzing skeletal muscles prevents the development of high airway pressures due to the patient bucking or fighting the ventilator. Notably, a side effect of neuromuscular blocking agents can be severe bronchospasm. Vecuronium is often reported to be unlikely to cause bronchospasm, but case reports suggest that vecuronium too can rarely cause bronchospasm [126]. Another adverse effect of these agents is that patients who undergo even brief neuromuscular blockade in conjunction with corticosteroid administration have a risk of developing a prolonged and sometimes severe myopathy [127].

Because all patients with severe exacerbations of asthma are treated with corticosteroids, paralyzing agents should be avoided whenever possible. For patients who cannot be managed without neuromuscular blockade, continuous infusions of neuromuscular blocking agents should be avoided and muscle function should be allowed to recover partially between repetitive boluses.
Mechanical ventilation accomplishes the work of breathing, while the severely obstructed patient is treated intensively with inhaled bronchodilators and glucocorticoids. With this intensive pharmacologic therapy, mechanical ventilation usually can be discontinued in 1 to 3 days once discontinuation guidelines are met [107,128–130] (see Chapter 168). Some patients may require 2 to 4 weeks of mechanical ventilation, especially when pneumonia complicates an acute exacerbation of asthma.

Complications of Mechanical Ventilation

Serious complications have been reported as a result of mechanical ventilation for severe exacerbations of asthma [105–107,113,115,116]. Most of these are preventable or treatable if detected early. Problems with airway control, including traumatic and esophageal intubation, should always be anticipated. Intubation of the right mainstem bronchus is a serious problem of airway control because delivery of tidal volumes to one lung increases the risk of barotrauma. Once an airway is established and mechanical ventilation initiated, hypotension may occur because the high intrathoracic pressures that occur during mechanical ventilation during a severe asthma exacerbations impede venous return to the right ventricle of the heart. This is treated by administering intravenous fluids and adjusting tidal volumes, respiratory frequency, and inspiratory flow to decrease hyperinflation and intrinsic positive end-expiratory pressure.

Barotrauma is a major cause of morbidity and mortality among patients receiving mechanical ventilation for severe exacerbations of asthma [105–107,113,115,116]. High plateau airway pressures are associated with overdistended alveoli that rupture. Air may dissect along the bronchovascular interstitium and sometimes is evident on chest radiograph as parenchymal air cysts, linear air streaks emanating from the hila, and perivascular air halos [131,132]. As the air dissects centrally, mediastinal and subcutaneous emphysema develop. As an alternative, air from ruptured alveoli may dissect through the pleural surfaces into the pleural space to create a pneumothorax [133]. Ultrasound examination has high sensitivity for the rapid bedside detection of pneumothorax and should be considered for every ICU patient with deterioration of gas exchange or respiratory function. For patients on mechanical ventilation, pneumothorax progresses to tension pneumothorax rapidly and should always be treated immediately with tube thoracostomy. It must be presumed, emergently, that any pneumothorax during mechanical ventilation is under tension [134]. (See Chapter 166 for the discussion of minimizing barotrauma during mechanical ventilation.)
Mucous plugging commonly occurs during acute exacerbations of asthma. Large mucous plugs occluding the endotracheal tube should be considered when there is insurmountable difficulty ventilating a patient. Large mucous plugs also may cause lobar or lung atelectasis that impairs gas exchange and increases airway pressures. Cautiously, therapeutic bronchoscopy may be considered to relieve large mucous plugs if conservative measures, corticosteroids, and bronchodilators are not effective. Retained secretions and atelectasis also contribute to the significant risk of nosocomial pneumonia during mechanical ventilation [135].

Other complications are indirectly related to mechanical ventilation. Thromboembolism and gastric stress ulcers may occur with greater frequency in patients with severe exacerbations of asthma [136]. Arrhythmias and hypokalemia may occur during treatment for acute asthma because of therapy with sympathomimetic drugs. Hypophosphatemia may develop secondary to alkalosis [137].

Additional and Unconventional Management Measures

Even after using bronchodilators, corticosteroids, sodium bicarbonate, and mechanical ventilation, airway obstruction sometimes is sufficiently severe to prevent maintenance of an acceptable arterial pH or adequate tissue oxygenation. In these rare cases, additional, sometimes unconventional, measures can be used to support the patient until corticosteroids have had time to suppress the underlying inflammatory process. Some of these measures are based only on anecdotal experience (Table 172.7).

If airway pressures remain high on mechanical ventilation despite the proper application of controlled hypoventilation with permissive hypercapnia, delivering heliox by mechanical ventilation has been suggested to allow adequate ventilation of the patient at reduced airway pressures [138]. Caution is necessary when using heliox in this setting because the low density of the gas mixture makes ventilator settings inaccurate (e.g., tidal volume) [139].

Bronchospasm usually is not the major factor limiting airflow of patients who are already being maximally treated for an acute exacerbation of asthma. However, for those who fail to respond to maximal conventional therapy, a variety of strategies have been advocated to maximize bronchodilation by relaxing airway smooth muscle. Some reports suggest that intravenous $\beta_2$-adrenergic agonists may significantly improve airway obstruction in select patients, but this treatment is not established and not recommended by current guidelines, in part because of danger of cardiac toxicity [1,2]. General anesthetics are excellent bronchodilators and an important option for patients whose conditions are refractory to maximal routine therapy. Anecdotally, halothane [140,141], thiopental [142], ketamine [143,144], and isoflurane [145] all have been used successfully to treat patients with severe asthma exacerbations. If general anesthetics are used, an anesthesiologist should be consulted.

Because a major cause of airway obstruction during an acute exacerbation of asthma is mucous plugging, therapeutic bronchoscopy with lavage has been used as an additional supportive measure for intubated patients who are extremely difficult to ventilate adequately [146–148]. While therapeutic bronchoscopy is not performed routinely because worsening bronchospasm is a recognized complication of bronchoscopy among asthmatics, when necessary because standard therapy has failed, a flexible bronchoscope with a large suction channel should be used, and the mechanically ventilated patient should be sedated. $N$-acetylcysteine, a mucolytic agent, is associated with bronchospasm in asthmatic patients but, anecdotally, has been used successfully during therapeutic bronchoscopy by delivering a dilute solution (less than 1%) through the bronchoscope to dissolve mucous plugs [146]. DNase (2.5 mg in 10 mL of sterile normal saline) has been administered through a bronchoscope to relieve mucous plugging causing atelectasis in a child with asthma [149].

Case reports describe unconventional measures that might be considered for the management of rare, exceedingly difficult cases. For
example, hypothermia and extracorporeal life support have been methods used to support critically ill patients whose conditions are refractory to conventional therapies [150,151].

Advances in asthma, based on randomized, controlled trials or meta-analyses of such trials, are summarized in Table 172.8.

16. Greally P: Human recombinant DNase for mucus plugging in status

An acute exacerbation of chronic obstructive pulmonary disease (AECOPD) is defined as “an event in the natural course of the disease characterized by a change in the patient’s baseline dyspnea, cough, and/or sputum that is beyond normal day-to-day variations, is acute in onset, and may warrant a change in regular medication” (GOLD) [1]. AECOPDs contribute to morbidity, mortality, and reduced quality of life and also constitute the most important direct health care costs associated with COPD. The economic costs of COPD are considerable and have been increasing. In 1993, it was estimated to be >$15.5 billion in the United States, 6.1 billion of which corresponded to hospital stays [2]. In 2010, the cost to the United States for COPD was projected to be approximately $49.9 billion, including $29.5 billion in direct health care costs, $8.0 billion in indirect morbidity costs, and $12.4 billion in indirect mortality costs [3]. There is also a correlation between disease severity in terms of GOLD stage and health care cost [4]. The costs of inpatient care are estimated to represent 40% to 57% of the total direct costs generated by patients with COPD [2]. Exacerbations of COPD are important because they negatively affect quality of life, are associated with accelerated rates of decline of lung function for those with COPD, and are associated with significant morbidity and mortality. The goals of treatment for COPD exacerbations are to minimize their impact, recognize their significance, and try to prevent subsequent exacerbations.
RISK FACTORS FOR AECOPD

Exacerbations of COPD can be precipitated by several factors. The most common causes appear to be infection of the tracheobronchial tree with either bacteria or viruses; a minority are caused by eosinophilic inflammation similar to asthma and about 30% are of unknown cause. Environmental pollution has been linked with poorer respiratory symptoms, increased acute exacerbations, and COPD-associated mortality [5]. Because these phenotypes are clinically indistinguishable [6], methods for differentiating phenotypes are a current focus of research. For example, blood eosinophilia may be a method to identify a subgroup of COPD patients with steroid responsive exacerbations [7]. We know that exacerbations beget exacerbations, so factors associated with exacerbations are a history of previous exacerbation, increasing disease severity and comorbidities [8].
The hallmark of COPD is airflow limitation measured by forced expiratory volume in 1 second to forced vital capacity (FEV<sub>1</sub>/FVC) ratio <0.7 [9]. This is caused by increased resistance of the small conducting airways from peribronchial fibrosis and increased smooth muscle mass, mucous, and goblet cell hyperplasia. Emphysematous parenchymal destruction increases lung compliance and leads to early airway collapse. There are a variety of theories underlying these changes in the lung, but it is generally accepted that they are the result of “host factors” and exposures (i.e., chronic innate and adaptive inflammatory immune response of the host to a lifetime exposure to “environmental factors” such as inhaled toxic gases and particles) [10]. The natural history of COPD has a long preclinical stage of between 20 and 40 years during which time changes can be occurring in the lung. As the lung ages, FEV<sub>1</sub> deteriorates from about 35 years of age onward at a rate of about 25 to 30 mL per year in normal individuals and at an accelerated rate in susceptible smokers at about 60 mL per year [11]. People with normal rates of decline can develop COPD if they have achieved a low peak level of FEV<sub>1</sub> [11]. Symptoms are usually absent until 40% of FEV<sub>1</sub> has been lost. The airflow obstruction of COPD is caused by pathologic changes in the small conducting airways (<2 mm in diameter) that contribute about 25% to total airway resistance in healthy individuals. The changes include disruption of the epithelial barrier, mucus hyperplasia, and Goblet cell metaplasia that result in accumulation of mucous plugs in the small airway lumen, infiltration of the airway walls by inflammatory cells, smooth muscle hypertrophy, peribronchiolar fibrosis, and deposition of connective tissue in the airway wall [12]. These changes in the airway walls result in reduced cross-sectional area and impair the ability to increase caliber with lung inflation. These changes have been correlated with disease progression from GOLD stages 0 to 4 [13]. Emphysematous lung destruction is associated with a similar inflammatory infiltration of alveoli and airway walls. This causes abnormal dilation of the airways distal to the terminal bronchioles, perforations in alveolar walls, and obliteration of airway walls that coalesce to form bullae destroying large volumes of lung tissue [14]. This leads to both loss of lung elastic recoil and loss of anatomic tethering of small airways. Emphysema has been subtyped depending on its pattern of distribution in the lung. The centrilobular pattern of emphysematous destruction usually has an upper lobe predilection and is closely associated with cigarette smoking. The panacinar pattern of emphysema is usually more marked in the lower
lobes and is characterized by a more uniform involvement of the acinus and is associated with α-1 antitrypsin deficiency [15].

Respiratory failure associated with COPD is usually a combination of lung failure and pump failure. Lung failure refers to the destruction of lung units, the alveoli and vascular beds, leading to reduced ventilation–perfusion (V/Q) matching and shunt [16]. Pump failure refers to mechanical disadvantage owing to increased workload, impaired chest wall and respiratory muscle performance, and impaired central or peripheral motor neuron function [17].

During AECOPD, inflammation within the lungs causes dynamic changes to occur. Increased bronchospasm and mucus hypersecretion results in further narrowing of the airway lumen and airflow limitation. Hypoxemia, anxiety, increased metabolic rate, and acidosis lead to an increased respiratory rate that shortens expiratory time and results in an increase of end-expiratory lung volume (EELV). This results in air trapping, which when extensive, leads to dynamic hyperinflation. The increase in EELV produces a positive alveolar pressure known as intrinsic positive end-expiratory pressure (PEEP). Intrinsic PEEP can occur with inappropriate ventilator settings (e.g., inappropriately high levels of minute ventilation or settings that result in insufficient expiratory time for exhalation relevant to the intrinsic ability of the lungs to passively exhale). Intrinsic PEEP can be associated with cardiac compromise, increased barotrauma, and alter the hemodynamic wave tracings during central venous pressure and pulmonary artery catheter monitoring. Dynamic hyperinflation leads to suboptimal muscle length to tension relationship and mechanical disadvantage for the muscles of respiration [18]. These changes induce severe dyspnea, increase dead space fraction, and aggravate V/Q relationships resulting in hypoxemia and, when severe, hypercapnia. Resolution of exacerbation and improvement in symptoms correlate well with an improvement in FEV₁, inspiratory capacity, and reduced EELV [19].
Knowledge about prognosis of AECOPD and factors that predict poor outcomes is important to enable intensive care unit (ICU) physicians to advise patients and families on the expected natural course of an illness, the likelihood of complications, and mortality \[^{20}\]. Prognoses based on clinical judgment alone have been shown to be inherently uncertain and vulnerable to unconscious bias \[^{21}\]. An accurate assessment tool like the numerous pneumonia scoring systems would be helpful. Currently, there is no assessment tool recommended by the major respiratory societies. Those available have not undergone external validation outside the population they were derived from, limiting there generalizability. Most of the scores have an area under the receiver operator curve of between 0.7 and 0.8, suggesting that they are only of moderate accuracy \[^{22}\].

Singanayagam et al. \[^{22}\] in a systematic review of the literature on predictors of mortality identified 12 factors with a consistent and statistically significant association with short-term mortality: age, male sex, low body mass index (BMI), cardiac failure, chronic renal failure, long-term oxygen therapy (LTOT), lower limb edema, GOLD stage 4, cor pulmonale, acidemia, confusion, and elevated plasma troponin level. In the subanalysis of patients managed in the ICU, three factors were associated with increased mortality: age, reduced Glasgow Coma Scale score, and acidemia. Messer et al. \[^{23}\] reviewed the literature specific to management of AECOPD in the ICU for markers of intermediate-term mortality. They found that time spent in the hospital prior to ICU admission, low Glasgow Coma Scale on admission to the ICU, cardiorespiratory arrest prior to ICU admission, cardiac dysrhythmia prior to ICU admission, and higher values of acute physiology scoring systems were all prognostic of in-hospital mortality. Interestingly, they found a number of premorbid variables as not being associated with increased intermediate-term mortality, and these were age, functional capacity, oral steroid use, spirometry, previous ICU admission, BMI, smoking status, and LTOT.
ANTIBIOTICS AND BIOMARKERS

Overuse of antibiotics in the ICU is common and accelerates the development of drug resistance [24]. Quality ICU care involves the judicious use of antibiotics; the reduction of antibiotic prescription rates has been shown to reverse the occurrence of nosocomial infection and drug-resistant organisms [25]. However, the importance of antibiotics can be highlighted by the fact that mortality rates for patients in septic shock increase by 7% per hour within the first 6 hours of delayed antibiotic administration [26]. Patients with sepsis from ventilator-associated pneumonia who had a delay of more than 24 hours after diagnosis until initiation of antibiotics have a sevenfold higher mortality rate compared to those started on adequate therapy earlier [27].

Systematic reviews [28] of COPD exacerbations suggest that antibiotics have large and consistent beneficial effects across outcomes of patients admitted to ICU. They have not been shown to be as useful in mild-to-moderate exacerbations of COPD [28]. Recent strategies to reduce antibiotic overuse have included the development of biomarker-directed treatment algorithms wherein antibiotics are given or withheld depending on the level of biomarkers measured in the blood. Biomarkers that have been studied are highly sensitive C-reactive protein and procalcitonin. Procalcitonin is currently the most promising. Procalcitonin-guided therapy has been effective for reducing antibiotic use by approximately 40% to 50% in hospitalized patients presenting with acute lower respiratory tract infection symptoms [29–32]. In all of these randomized controlled studies, there was no increase in adverse events among patients who had antibiotics de-escalated.
Oxygen

All patients with COPD exacerbations have the potential to develop hypoxemia and hypercapnia. We recommend an arterial blood gas to assess the degree of hypoxemia and hypercapnia. Supplemental oxygen therapy should be administered to patients suffering an exacerbation of COPD to maintain oxygen saturations between 88% and 92%, being careful to avoid hyperoxemia. Generally, the use of controlled oxygen therapy titrated to an acceptable goal of oxygen saturation (usually 88% to 92%) is considered appropriate [33].

Avoidance of hyperoxemia is important because of the well-described occurrence of worsening hypercapnia. There is evidence to show the indiscriminate use of oxygen therapy increases mortality and need for intubation [33]. The induction of hypercapnia through hyperoxemia is still poorly understood. It is thought to be a combination of mostly change in V/Q mismatch, with a mild decrease in central respiratory drive and the Haldane effect [34]. The ability of the lungs to shunt blood away from areas of low alveolar oxygen tension is disrupted by the administration of high levels of oxygen; the resultant change in V/Q matching leads to increased dead space. The Haldane effect describes the binding ability of hemoglobin for CO₂ was increased oxygen shifts the hemoglobin CO₂ dissociation curve to the right and leads to an increase in PacO₂. Patients who are already ventilating at their maximum are unable to increase minute ventilation further to counteract this.

High-flow nasal oxygen devices are increasingly used in critical care. There is a growing evidence base for their use in hypoxemic respiratory failure, but this form of oxygen therapy has been poorly studied in hypercapnic respiratory failure. One of the benefits of high-flow oxygen systems is the washout of CO₂ from anatomic dead space, effectively converting the oropharynx and conducting airways into a reservoir. The higher flow rates delivered match the patients inspiratory flow more effectively [35]. There is a small amount of PEEP delivered to the airway that can recruit lung units or potentially offset intrinsic PEEP. Probably, the greatest benefit is a reduced respiratory rate that leads to less air trapping. Evidence for the use of high-flow oxygen therapy in severe COPD or hypercapnic respiratory failure is limited mainly to case reports and a small study on exercise capacity [36,37]. A detailed discussion of oxygen therapy and delivery devices can be found in Chapter 169.
Bronchodilators

Patients in AECOPD have increased expiratory flow limitation. Nebulized short-acting bronchodilators are used to reduce bronchospasm. These medications have not been robustly studied in severe COPD exacerbations requiring critical care.

β-Agonists

Short-acting β-agonists include albuterol and levalbuterol. These drugs are selective β₂ receptor agonists that induce smooth muscle relaxation and relief of bronchospasm. They can be administered via inhaler or by nebulizer. They have been shown in randomized controlled trials and meta-analyses to improve symptoms and lung function [38,39]. Common side effects include tremor, tachycardia, and hypokalemia.

Anticholinergics

The short-acting anticholinergic ipratropium bromide blocks muscarinic acetylcholine receptors, thus promoting smooth muscle relaxation and inhibition of mucus secretion. These medications improve lung function and PaO₂ [38,40]. Common side effects include dry mouth, nausea, tachycardia, and sedation. There is a concern that nebulized anticholinergics may precipitate worsening glaucoma by coming into contact with the eyes in susceptible individuals.

In general, we use a combination of nebulized short-acting β-agonist and anticholinergic. A detailed discussion of inhaled bronchodilator therapy can be found in Chapter 169.

Antibiotics

Antibiotics are an intervention that is of proven benefit in AECOPD requiring ICU admission [28]. One must take into account potential pathogens, local resistance patterns, and antibiotic stewardship. The most common bacterial pathogens are Haemophilus influenzae, followed by Streptococcus pneumoniae, Moraxella catarrhalis, and Pseudomonas aeruginosa, and the common viral pathogens are Rhinovirus, Parainfluenza, Influenza, and Respiratory Syncytial Virus [41].

Prompt appropriate antibiotic therapy is the correct management of patients with severe COPD and symptomatic exacerbations that include at least two of the three cardinal symptoms (increased sputum purulence,
volume or increased dyspnea; anthonisen type I or II exacerbations) [9].

**Antivirals**

Viral infections, in particular rhinovirus, account for approximately 30% of COPD exacerbations, and a variety of potential therapeutic agents have been investigated. Unfortunately, although the neuraminidase inhibitors such as oseltamivir and zanamivir are effective against influenza [42], antirhinoviral medications have failed to demonstrate a clinically significant benefit [43]. We do not routinely test for viral exacerbations outside the influenza season.

**Steroids**

Corticosteroids are routinely used for the treatment of COPD exacerbations. The evidence for the use of corticosteroids for COPD exacerbations admitted to the ICU is extrapolated from studies of individuals with milder disease [44]. To further confuse this picture, there is now evidence to support the use of systemic steroids in severe pneumonia [45], an often-coexisting diagnosis in exacerbations of COPD. We know that corticosteroids speed the recovery of FEV₁ and FVC in conjunction with bronchodilators [44]. Corticosteroids reduce the length of hospital stay and the risk of treatment failure in the first 3 months [46]. In two small studies performed in critically ill patients requiring ventilator support, there were conflicting results [47,48]. Clearly, some patients respond to steroid therapy and some do not, and this probably reflects the underlying inflammatory profile. Bafadhel et al. [49] showed peripheral blood eosinophil count as a promising biomarker to direct corticosteroid therapy during COPD exacerbations. The most appropriate dose is unclear and is generally at the discretion of the treating physician. The dosage should be cut down once a therapeutic response is evident and converted to oral once the patient is able to swallow. We acknowledge that there are adverse effects of corticosteroids with high dosage and extended treatment durations, but the current evidence base does not determine the most appropriate regimen. For patients admitted with very severe COPD exacerbations, we use methylprednisolone 40 mg every 6 hours consistent with the original study by Albert et al. [50].

**Heliox**

Helium is an inert gas that in combination with oxygen (heliox) has a lower density than oxygen and nitrogen. Heliox is a mixture of variable concentrations of helium and oxygen (60% to 80% helium and 40% to 20% oxygen). The benefit of using a lower density gas is its ability to
improve flow in large airways where airflow is turbulent relative to laminar airflow. The increase in flow acts to decrease airway resistance and the work of breathing. In COPD, the addition of heliox to noninvasive ventilation (NIV) decreases respiratory effort and intrinsic PEEP, but does not improve outcomes such as requirement for intubation or mortality [51]. We do not routinely use heliox in the treatment of patients with AECOPD. A detailed discussion of heliox therapy can be found in Chapter 169.

**Ventilatory Support**

Indications for ventilator support in COPD patients include:

- Unsustainable increased work of breathing
- Severe hypoxemia
- Exacerbation leading to hypercapnia with reduced pH <7.35

**Noninvasive Ventilation**

The main benefits associated with noninvasive positive-pressure ventilation (NIPPV) in AECOPD are lower rates of intubation, shorter length of stay, and lower rates of the complications of invasive mechanical ventilation (MV). It has been shown to reduce the need for intubation, decrease length of stay, decrease mortality, and, in some areas, conserve the precious resource of ICU beds [52,53]. Patients with COPD who present with exacerbation and hypercapnic respiratory failure with acidosis (pH < 7.35) are the group most likely to benefit from NIPPV. Exacerbations increase the work of breathing often exceeding the patient’s ability to compensate and result in hypoventilation. Increased intrinsic PEEP, dynamic hyperinflation, and weakened respiratory muscle force combine to produce ineffective tidal volume. NIV effectively unloads the respiratory muscles, increases tidal volume, reduces the respiratory rate, offsets intrinsic PEEP, and decreases the diaphragmatic work of breathing. These changes lead to more efficient ventilation with improved oxygenation and reduction in hypercapnia.

For effective treatment, NIV needs to be used for appropriate groups of patients, and combined with treatment of the underlying condition with bronchodilators, corticosteroids, and antibiotics. Exacerbations of COPD are ideally suited for treatment with NIV support, given the reversibility of exacerbations with treatment. However, failure rates of NIV of approximately 20% have been reported from controlled trials and may be much higher in some real-world settings [52]. We recommend prospectively establishing a management plan for NIPPV failure that
takes the patient’s wishes, comorbidities, and baseline functional status into consideration. If MV is felt to be inappropriate, goals of care should include symptom palliation and ongoing medical care [54]. A detailed discussion of NIPPV and how to institute it and deliver it can be found in Chapter 167.

Invasive Mechanical Ventilation

Indications for invasive mechanical ventilator support include:

- Reduced conscious level
- Inability to adequately control secretions
- Need for controlled ventilation with the use of sedation
- Persistent or worsening hypoxemia and/or worsening respiratory acidosis despite supplemental oxygen or NIPPV
- Hemodynamic instability and need for vasopressors

The goal of MV is to provide adequate respiratory muscle rest, improve gas exchange, and allow time for exacerbation resolution while not causing further harm.

Ventilator Settings

In general, initial ventilator settings are operator dependent and vary with local practices. We recommend the initial use of assist-control (AC) ventilation for invasive MV of AECOPD. AC ventilation is the most efficient at decreasing the work of breathing in COPD patients [55].

A major issue during ventilation for obstructive lung diseases (asthma and COPD) is the development of dynamic hyperinflation (interchangeable with auto-PEEP or intrinsic PEEP) [18]. This refers to increased EELV and the pressure it exerts. Dynamic hyperinflation can be minimized by reducing minute ventilation, prolonging expiration to allow deflation, and by reducing airflow resistance with targeted medication (Fig. 173.1).
Inset of ventilator interface showing the effects that minute ventilation, respiratory rate, and inspiratory flow have on I:E ratio. Note that reducing the rate from 24 to 14 breaths per minute and increasing the inspiratory flow from 50 to 75 L per minute, the I:E ratio changes from 1:1.6 to 1:5.5. Also, note in A (below left) that the expired gas volume does not return to zero, leading to trapped air and intrinsic PEEP. I:E, inspiration:expiration; PEEP, positive end-expiratory pressure.

The aim of controlled ventilation should be to match minute ventilation to metabolic requirements while avoiding dynamic hyperinflation, lung injury, and extreme respiratory acidosis. It may be
necessary to aggressively sedate the patient to achieve synchrony with the ventilator and reduce tachypnea. When selecting a tidal volume, it is important to provide sufficient volume to satisfy the patient and achieve synchrony with the ventilator. As guidance, tidal volumes of 5 to 8 mL per kg are often used [56].

When estimating the appropriate minute ventilation, it is important to be aware that, for many patients with severe COPD, the baseline state is a chronic compensated respiratory acidosis. For most individuals without chronic respiratory failure, we aim for a PaCO$_2$ 40 mm Hg, but, in this patient group, we aim to achieve their steady-state (baseline) PaCO$_2$ because this reflects the balance of their central respiratory drive and the ability of their lungs to ventilate. This can be estimated from stable blood gas records or serum bicarbonate (PaCO$_2$ = 1.5 * [HCO$_3$] + 8 ± 2).

Ventilator settings that produce a “normal” PaCO$_2$ in an individual with a chronic respiratory acidosis will lead to renal loss of bicarbonate. This can result to significant alkalosis (i.e., posthypercapnic metabolic alkalosis) with its potential central nervous system and cardiovascular complications, and difficulty when attempting to wean from the ventilator.

Optimization of the inspiration:expiration (I:E) ratio will reduce hyperinflation, and, in severely obstructed patients, >1:4 is often effective [56]. Adjustment of inspiratory flow to shorten the inspiratory phase of each breath can lead to better gas exchange by prolonging the expiratory phase and allowing more complete exhalation. In addition, reducing the respiratory rate will increase the I:E ratio. As guidance, flow rates between 70 and 100 L per minute are appropriate depending on peak airway pressures. Use of low tidal volumes and high-flow rates can lead to short insufflation time, with the risk of double triggering if the patient continues effort beyond ventilator insufflation time. Double triggering can lead to high tidal volumes and increased EELV. In this situation, use of a longer inspiratory time may resolve this; options include switching from constant flow to a decelerating flow waveform, or by reducing peak flow and/or adding an inspiratory pause [57].

The trigger for initiation of each breath depends on the mode of ventilation chosen. For controlled ventilation, the trigger is time. However, during AC, the patient initiates the breath, and this is thought to be more comfortable. The ventilator detects changes in the patient’s effort and triggers a breath in response. Trigger types include pressure, volume, or flow. In pressure triggering, the patient must exert a predetermined amount of negative pressure to elicit a ventilator-assisted breath (−1 to −5 cm H$_2$O). In flow triggering, the patient’s effort decreases the bias flow in the ventilator circuit by a predetermined value (1 to 3 L per minute), which then initiates a breath. We generally use flow
triggering because it was thought to be more comfortable for the patient and can results in less work of breathing for some patients [17]. Patients with dynamic hyperinflation have greater difficulty triggering the ventilator. This is because they first must generate sufficient force to overcome the elastic recoil associated with the increased EELV (intrinsic PEEP) and then sufficient force to reach the trigger threshold [55].

The level of intrinsic PEEP can usually be estimated through the ventilator. Static intrinsic PEEP can be measured in patients without active respiratory effort. The ventilator executes an end-expiratory hold maneuver. This provides a measure of total PEEP by allowing lung units with different regional time constants to equalize with the ventilator. The intrinsic PEEP can then be calculated by subtracting the external PEEP from the total PEEP. For spontaneously breathing patients, the process is more complex and requires the use of esophageal pressure monitors and airflow tracings. Expiratory muscle activity and airway narrowing can all cause inaccurate measurements of intrinsic PEEP.

Elevated intrinsic PEEP can lead to nontriggered breaths that increase the work of breathing and sensation of dyspnea. In this situation, the addition of external PEEP set through the ventilator can decrease the inspiratory threshold load [18]. In general, setting external PEEP approximately 70% of the intrinsic PEEP is effective in patients with COPD. A reduction of nontriggered breaths is a good indication of more comfortable ventilator settings. The clinical assessment of the patient receiving MV is important in detecting the adequacy of patient ventilator interaction and respiratory distress. Analysis of ventilator waveforms can also provide vital information.

A detailed discussion of invasive ventilation and how to institute it and deliver it can be found in Chapter 166.

**Weaning from Mechanical Ventilation**

Patients with severe COPD can prove difficult when trying to liberate them from the ventilator. COPD patients can develop significant dynamic hyperinflation during weaning as a result of tachypnea and expiratory flow limitation. This will lead to respiratory distress and clinical signs of weaning failure [17]. All patients should be assessed for appropriateness of attempted weaning (Table 173.1) on a daily basis.

| TABLE 173.1 Selection of COPD |
Patients for Weaning from Mechanical Ventilation

Resolution of the underlying cause of respiratory failure
Stable hemodynamics without need for significant vasopressors
Stable metabolic state, that is, without sepsis or hyperthermia
Cessation of neuromuscular blocking agents
Patients should be alert, able to follow commands, and protect their airway
Metabolic and electrolyte derangement should be corrected
Adequate gas exchange, that is, PaO₂ to FiO₂ ratio greater than 200
Require minimal assistance from the ventilator, that is, PEEP ≤5 cm H₂O and FiO₂ ≤50%
Adequate respiratory muscle strength

Rapid Shallow Breathing Index

Multiple studies have reported the development of rapid shallow breathing in patients who fail weaning from the ventilator. The development of rapid shallow breathing, asynchronous or paradoxical thoracoabdominal movements, and accessory muscle recruitment during a spontaneous breathing trial are physical examination findings of an unsuccessful weaning trial. The degree of rapid shallow breathing can be quantified by calculating the ratio of respiratory frequency to tidal volume (f/VT) in liters. An f/VT ratio of <105 breaths/min/L has been shown to be the best predictor of weaning outcome [17], and has become part of the routine assessment of suitability for weaning from MV. It is important to recognize that this test is most accurate in patients who have received MV for less than 7 days.

Weaning Methods

There are three main types of weaning methods and these are daily spontaneous breathing trials, gradual reduction of pressure support (PS), and synchronized intermittent mandatory ventilation. Daily spontaneous breathing trials have been shown to be safe, effective, and faster at
liberating patients from MV [58]. Comparing PS and spontaneous breathing trials, current evidence does not indicate which of these is superior [59]. We generally opt for a spontaneous breathing trial using the continuous positive airway pressure mode through the ventilator circuit to take advantage of ventilator alarms with or without PEEP for 30 minutes to 2 hours. At 30 to 120 minutes, if the patient looks favourable, we will extubate to humidified oxygen to maintain O\textsubscript{2} saturations 88% to 92%. Occasionally, we favour extubation to NIV in patients who are marginal as long as they can manage their own secretions, are mentally unimpaired, and don’t have a difficult airway [60]. The development of rapid shallow breathing, asynchronous or paradoxic thoracoabdominal movements, and accessory muscle recruitment during a spontaneous breathing trial are physical examination findings indicating high risk for an unsuccessful trial of extubation [17]. When any of these findings are present, the patient should be placed back on ventilator support. Subsequently, there should be an assessment and correction of suspected causes of weaning failure.

A detailed discussion of weaning from MV can be found in Chapter 168.

**Tracheostomy**

Tracheostomy is commonly performed for mechanically ventilated patients with prolonged ventilator-dependent respiratory failure. Reasons to perform tracheostomy include the provision of a stable airway to facilitate rehabilitation, improved clearance of respiratory tract secretions and, in some cases, the reduction of sedation [61]. Sedation has been consistently associated with delirium and the length of ventilator-dependent respiratory failure [62]. Some patients appear to tolerate endotracheal intubation poorly and require sedation. In our experience, tracheostomy often reduces the need for sedation, because it can improve ability to communicate and reduce frustration.

Complications of tracheostomy include bleeding, fistula formation, infection, and tracheal stenosis [63]. The use of a tracheostomy as an adjunct to the weaning process in COPD can be helpful for appropriate patients. COPD patients can occasionally require long periods of MV to allow time for their exacerbation to resolve sufficiently to allow weaning. Failure of weaning from the ventilator in COPD is complex to understand, because it results from an imbalance between respiratory muscle capacity and the applied resistive and elastic loads [64]. Endotracheal tubes can be small in diameter, and the development of biofilm (debris lining the endotracheal tube) can further decrease the internal diameter, leading to a greater resistive load [64]. Several groups have studied the effects that tracheotomies have on the ability to wean
They found that tracheotomy significantly reduces work of breathing, the pressure time index, and measures of resistive and elastic workload.

A detailed discussion of endotracheal intubation and tracheotomy can be found in Chapters 8 and 9.
EXTRACORPOREAL LIFE SUPPORT, EXTRACORPOREAL CARBON DIOXIDE REMOVAL

Despite continued improvements in NIV, it is sometimes insufficient to overcome refractory hypercapnia and acidosis in AECOPD. In such cases, conversion to invasive MV is needed. This self-selecting group has a higher mortality up to 30% [66]. Mortality is increased because the patients are exposed to the associated risks of invasive ventilation, including ventilator-associated pneumonia [67], prolonged MV, and difficult weaning [68]. Advances in extracorporeal gas exchange technology have led to the evolution of systems designed for extracorporeal carbon dioxide removal (ECCO$_2$R). Currently, the evidence to support its use is based on case reports and small case series. Kluge et al. [69] studied 21 patients treated with ECCO$_2$R at the point of failing support with NIV and compared them retrospectively to a historic cohort treated with invasive MV. Of the 21 patients, 14 who were treated had an AECOPD. Ninety percent of the patients treated with the ECCO$_2$R did not require intubation and mechanical ventilatory support. There was no statistical difference in 28-day mortality or 6-month mortality. Burki et al. [70] also reported on a pilot study of ECCO$_2$R in COPD patients with hypercapnic respiratory failure. There were three groups of patients: group 1 consisted of 7 patients who were receiving NIV and had a high likelihood of requiring intubation, group 2 consisted of 2 patients who had failed two weaning attempts from continuous NIV support, and group 3 consisted of 11 patients already on invasive MV that were placed on ECCO$_2$R to assist with weaning. In the first group of patients, despite a mean arterial pH of 7.25 and PCO$_2$ of 83 mm Hg at baseline while on NIV, all seven avoided intubation and MV. Both patients in group 2 avoided invasive MV but remained on intermittent NIV support after weaning from ECCO$_2$R. In group 3, three patients were weaned off invasive MV, and, in three further patients, the level of invasive ventilatory support was reduced. Only one patient remained on the same level of ventilatory support. However, no patient in group 3 was able to be liberated from ventilator support altogether. The evidence from these studies would suggest that ECCO$_2$R is an effective therapeutic modality for CO$_2$ removal but not without its associated risks, and it does not
change the long-term survival. Complications related to the need for mobility limiting large-bore catheters, the need for anticoagulation, and the consequences of hemolysis and thrombocytopenia associated with ECMO all need to be considered. Patients who develop hypercapnic respiratory failure are at the severe end of the spectrum. The use of such lifesaving modalities should be seen as indication for consideration of lung transplantation or initiation of a palliative focused care plan.

**Nutrition**

Critical illness induces a highly catabolic state that can lead to loss of significant muscle mass. This catabolic state, prolonged immobility, and a series of other risk factors, including possible exposure to corticosteroids and paralytic agents, can contribute to critical care polyneuropathy [71]. Awareness of loss of respiratory muscle mass and diaphragm weakness is
extremely important because it can lead to difficulty weaning from MV [72]. Nutrition should not be neglected for patients who are stable enough to feed. Nutrition should be balanced to meet the body’s needs and avoid loss of muscle mass [73]. Unnecessary calories and excessive carbohydrate feeding can lead to carbon dioxide production which the patient’s compromised respiratory system may be unable to clear.

A detailed discussion of nutritional support in critically ill patients can be found in Chapters 212–214.

INTRODUCTION

Pulmonary hypertension, defined as a mean pulmonary artery pressure (mPAP) greater than 25 mm Hg, is a common finding among critically ill patients. It can be related to the underlying critical illness (respiratory failure, pulmonary embolism, decompensated heart failure), pre-existing conditions (left-sided heart disease, chronic obstructive pulmonary disease [COPD], and interstitial lung disease), or may be the primary cause of critical illness, because in the case of decompensated right heart failure due to pulmonary arterial hypertension (PAH). Initiation of appropriate therapy requires differentiating among these possible etiologies.
Pulmonary hypertension is classified into five groups based on similar pathology and response to treatment, according to the fifth World Symposium on Pulmonary Hypertension (Table 174.1) [1]. In this classification, groupings are based on whether the primary abnormality is in the precapillary arteries and arterioles (Group 1), postcapillary pulmonary veins and venules (Group 2), alveoli and capillary beds (Group 3), or due to chronic thromboemboli (Group 4). Group 5 comprises causes of pulmonary hypertension with multiple or unclear mechanisms.

Group 4. Chronic thromboembolic pulmonary hypertension
Group 5. Pulmonary hypertension with unclear multifactorial mechanisms
Hematologic disorders: chronic haemolytic anemia, myeloproliferative disorders, and splenectomy
Systemic disorders: sarcoidosis, pulmonary Langerhans cell histiocytosis, and lymphangioleiomyomatosis
Metabolic disorders: glycogen storage disease, Gaucher disease, and thyroid disorders
Others: tumoral obstruction, fibrosing mediastinitis, chronic renal failure, and segmental PH

PAH refers only to Group 1 and is distinct from other forms of pulmonary hypertension. PAH can be idiopathic (IPAH, formerly primary pulmonary hypertension or PPH), heritable (HPAH), or associated with underlying conditions such as collagen vascular disease, congenital heart disease, portal hypertension, HIV infection, and specific drugs (e.g., fenfluramine) or toxins (e.g., rapeseed oil). Pulmonary venous hypertension is the result of elevated pulmonary venous (e.g., sclerosing mediastinitis) or left-sided cardiac filling pressures that lead to passive elevation in pulmonary artery pressures (PAPs). This is typically caused by left ventricular (LV) systolic or diastolic heart failure, or valvular heart disease (mitral or aortic regurgitation or stenosis). Lung disease can cause pulmonary hypertension due to alveolar hypoxemia (hypoxic pulmonary vasoconstriction) and vascular destruction [2]. Chronic thromboembolic pulmonary hypertension (CTEPH) can be due to proximal and/or distal obstruction of the pulmonary vasculature by chronic thromboemboli.

Pulmonary hypertension related to critical illness can occur through multiple mechanisms, and therefore patients may fall into any of the
above-described groups (Table 174.2). However, no matter the group, or the reason for admission to the intensive care unit (ICU), right heart failure in this setting is associated with a poor prognosis. Among patients with PAH or inoperable CTEPH admitted to the ICU with decompensated right heart failure, infection is the most commonly identified trigger (approximately 25%), with other causes including drug or dietary noncompliance, arrhythmia, pulmonary embolism, and pregnancy. For approximately 50% of cases of decompensated right heart failure, no precipitating etiology can be identified, suggesting it is due to underlying disease progression. Decompensated right heart failure requiring ICU admission is associated with a high mortality rate (32% to 41%) [3,4].

Modified from Zamanian RT, Haddad F, Doyle RL, et al:
Decompensation of left heart disease can cause or worsen pulmonary venous hypertension. Exacerbations of chronic hypoxemic lung disease (chronic obstructive lung disease or interstitial lung disease) can be associated with pulmonary hypertension. Acute pulmonary embolism can cause pulmonary hypertension, depending on the degree of vascular obstruction. For a patient with normal pulmonary vasculature, greater than 50% obstruction of the pulmonary vasculature must occur before pulmonary hypertension occurs. Pulmonary hypertension may also occur following acute pulmonary embolism with a lesser degree of pulmonary vascular obstruction among patients with underlying cardiopulmonary disease [5].

Pulmonary hypertension complicates most cases of acute respiratory distress syndrome (ARDS), reported for 73% to 92% of patients with ARDS [6,7]. However, it is almost always mild to moderate in severity; in one study, only 7% of patients with ARDS had severe pulmonary hypertension [7]. The magnitude of pulmonary hypertension in ARDS appears to be related to the severity of lung injury [8]. Approximately 25% of patients with ARDS have findings of right ventricular (RV) failure as detected by echocardiography [8–10]. It has been suggested that the incidence of RV failure in ARDS has decreased with widespread adoption of low tidal volume ventilation. The prognostic significance of pulmonary hypertension and RV failure for patients with ARDS is uncertain, with multiple studies yielding conflicting results [6,8,11,12].
The pulmonary circulation is the only vascular bed that accommodates the entire cardiac output while maintaining both low pressure and low vascular resistance. Normally, the pulmonary vasculature is able to accommodate increases in cardiac output without increases in pressure or resistance via dilation of pulmonary vessels and recruitment of previously closed vessels [13]. Pulmonary hypertension develops when abnormalities of the pulmonary vasculature lead to increases in pulmonary vascular resistance (PVR) and therefore increased RV afterload.

Because the RV normally ejects blood against a significantly lower afterload than the LV, it has a thinner wall and is therefore more compliant. This allows it to accommodate large increases in volume (preload). However, increases of afterload result in proportionate decreases of RV stroke volume [14]. Decreased RV stroke volume reduces blood return to the LV, thereby decreasing cardiac output. In addition, RV pressure overload causes “ventricular interdependence,” in which elevated right ventricular end-diastolic pressure (RVEDP) causes bowing of the interventricular septum toward the LV during diastole, preventing LV diastolic filling and further reducing cardiac output [13]. RV pressure overload can also open the foramen ovale, allowing the shunting of blood from right to left, with resultant hypoxemia [14].
Patients with PAH share common pathologic findings including intimal fibrosis, increased medial thickness, pulmonary arteriolar occlusion, and plexiform lesions [15]. Multiple molecular pathways involved in the pathogenesis of IPAH have been identified. Patients with IPAH have an increase in mediators of vasoconstriction and vascular smooth muscle cell proliferation (thromboxane A2, Endothelin-1) and a decrease of substances that promote pulmonary vasodilation and inhibition of vascular smooth muscle cell proliferation (prostacyclin, nitric oxide, and vasoactive intestinal peptide) [16].

Pathologic findings of pulmonary hypertension associated with ARDS vary with the time course of illness. Micro- and macrothrombi have been demonstrated in most patients. Early in disease, there are findings of acute endothelial cell injury. During the intermediate phase, chronic capillary changes, fibrocellular obliteration of arteries, veins, and lymphatics can occur. Vascular remodeling with distorted, tortuous arteries and veins, arterial muscularization, and reduced capillary number are seen during the late stages [8].
DIAGNOSIS

Signs and Symptoms
Patients with PAH typically present with exertional dyspnea. Other presenting symptoms may include fatigue, syncope or near syncope, palpitations, and chest pain. Because the disease progresses, patients may develop symptoms referable to reduced cardiac output and RV failure including fatigue, abdominal bloating and distension, and lower extremity edema. The presence of orthopnea and paroxysmal nocturnal dyspnea is suggestive of pulmonary venous hypertension [17].

Signs of elevated PAP on physical examination include (a) prominent pulmonary component of the second heart sound or P2, (b) RV heave, (c) early systolic ejection click, (d) midsystolic ejection murmur, (e) RV S4 gallop, and (f) prominent jugular “a” wave. With more advanced disease, patients may develop findings of tricuspid regurgitation, including a holosystolic murmur along the left lower sternal border, and elevated jugular venous pressure. Findings of RV failure include elevated jugular pressure, pulsatile hepatomegaly, peripheral edema, ascites, and hypotension [17,18]. Patients with non–Group 1 causes of pulmonary hypertension may also have findings related to the primary disease, such as wheezing, decreased breath sounds and prolonged expiratory phase in COPD, and crackles in interstitial lung disease. The presence of bruits over the lung fields is more specific for CTEPH, although present in only 30% of these patients [19].

Diagnostic Testing
Electrocardiography (ECG) findings suggestive of pulmonary hypertension include right axis deviation (RAD), right atrial enlargement (P-wave ≥ 2.5 mm), and right ventricular hypertrophy (RVH) [17]. However, ECG is not sufficiently sensitive or specific to screen patients suspected of PAH [20]. ECG findings in patients with IPAH have prognostic significance with findings of P-wave amplitude 2.5 mV or more in lead II, qR lead V1, and RVH by WHO criteria associated with significantly increased risk of death, even after controlling for hemodynamic parameters, functional class, and treatment [18,20,21].

Radiographic findings of pulmonary hypertension include enlarged
main and hilar pulmonary arterial shadows (≥18 mm diameter in men, 
≥16 mm diameter in women) with peripheral pulmonary vascular 
attenuation (pruning) and RV enlargement as evidenced by decreased 
size of the retrosternal clear space [20,22]. Other radiographic findings 
may suggest an underlying cause for pulmonary hypertension such as 
hyperinflation (COPD), prominent interstitial markings and fibrosis 
(interstitial lung disease), or cephalization and Kerley B lines (left-sided 
congestive heart failure).

Computerized tomography may be helpful in further delineating 
underlying parenchymal lung disease. Ventilation/perfusion (V/Q) 
scanning is the test of choice for identifying CTEPH; however, this cannot 
be performed on intubated patients and may be difficult to obtain in 
unstable patients, limiting its utility in critically ill patients. A normal or 
low probability V/Q scan virtually excludes the diagnosis of CTEPH 
[23]. Computerized tomographic angiography (CTA) can identify acute 
pulmonary emboli and often CTEPH as well. However, CTA has been 
found to be less sensitive than V/Q scanning at identifying CTEPH, and 
may underestimate the clot burden in this condition [23].

Laboratory evaluation may reveal underlying diseases associated with 
an increased risk of pulmonary hypertension, such as connective tissue 
disease positive antinuclear antibody (ANA), or HIV infection. Brain 
natriuretic peptide (BNP) may have prognostic value in patients with 
PAH [20]; however, BNP levels may be elevated in critically ill patients 
with shock, or cardiac dysfunction of any cause and is, therefore, a 
nonspecific finding of unclear clinical significance [14,24].

Pulmonary hypertension may be suggested among critically ill patients 
by echocardiography. Echocardiography can provide noninvasive 
estimates of pulmonary arterial pressures, assessment of right and LV 
function, and evaluation of valvular disease. Echocardiographic findings 
of pulmonary hypertension may include RV dilation and hypertrophy, D-
shaped LV due to septal bowing in the LV during late systole, RV 
hypokinesis, tricuspid regurgitation, right atrial enlargement, and a 
dilated inferior vena cava (IVC) [13,20]. Echocardiography can provide 
prognostic information, with measures of RV dysfunction associated with 
worse outcomes, including increased RV diameter, a decreased tricuspid 
annular plane systolic excursion (TAPSE), an elevated RV myocardial 
performance index (Tei index), increased right atrial diameter, and the 
presence of a pericardial effusion [18]. Although echocardiographic 
estimates of PAP correlate well with invasively measured PAP for patients 
with left-sided heart disease [25], multiple studies have demonstrated 
that echocardiographic estimates of PAP for patients with suspected 
pulmonary hypertension or with underlying lung disease can be 
inaccurate; the false-positive rate is 30% to 40% under these 
circumstances [26–29].
Therefore, right heart catheterization remains the gold standard for diagnosis of pulmonary hypertension and must be performed to confirm the diagnosis, determine the appropriate etiology, and determine the treatment. As stated previously, pulmonary hypertension is defined as an mPAP of more than 25 mm Hg, measured by right heart catheterization. The finding of a pulmonary capillary wedge pressure (PCWP) greater than 15 mm Hg is indicative of pulmonary venous hypertension. Right heart catheter findings may include the following hemodynamic profiles: (a) elevated PAP, normal PCWP, elevated PVR, consistent with PAH or PH due to hypoxemic lung disease; (b) elevated PAP, elevated PCWP, normal pulmonary artery diastolic pressure (PAD)–PCWP gradient, consistent with pulmonary venous hypertension; and (c) elevated PAP, elevated PCWP, elevated PAD–PCWP gradient, consistent with pulmonary venous hypertension with an “active” component. Among patients with IPAH, findings at right heart catheterization of mPAP greater than or equal to 85 mm Hg, right atrial pressure (RAP) greater than or equal to 20 mm Hg, and cardiac index (CI) less than 2 L/min/m² an association with lower rates of survival has been reported [18].

Vasodilator testing may be performed at the time of right heart catheterization. This is done by measuring baseline hemodynamics, administering a short-acting pulmonary vasodilator (adenosine, inhaled nitric oxide [iNO], or prostacyclin), and then repeating the hemodynamic measurements. Vasodilator responsiveness is defined as a decrease of the mPAP by at least 10 mm Hg, to less than 40 mm Hg with no change or an increase of cardiac output [30]. Vasodilator responsiveness for patients with IPAH is predictive of response to treatment with high-dose calcium-channel blockers and suggests a better prognosis. Of note, patients with IPAH who are not acutely vasodilator responsive respond to long-term treatment with pulmonary vasodilators [31]; therefore, the finding of vasodilator responsiveness should only be used to decide which patients might be treated with calcium-channel blockers, not which patients should be treated in general. The clinical significance of vasodilator responsiveness for forms of pulmonary hypertension other than IPAH is unproven.
Treatment of pulmonary hypertension is dictated by the underlying cause, according to the revised classification of pulmonary hypertension (Table 174.1). When treating pulmonary hypertension in the ICU, one must differentiate between patients with pulmonary hypertension associated with underlying critical illness and patients who are critically ill due to PAH with RV failure and hemodynamic compromise.

General Measures

Hypoxic pulmonary vasoconstriction may contribute to the pulmonary hypertension of critically ill patients. Supplemental oxygen results in a small, but statistically significant, decrease of PVR and an increase in cardiac output for patients with pulmonary hypertension of diverse etiologies [32]. Therefore, maintaining adequate oxygenation for critically ill patients with pulmonary hypertension is an important therapeutic goal.

Optimal fluid management in critically ill patients with decompensated RV failure can be extremely challenging. Because the RV is preload dependent, hypovolemia can result in decreased preload and therefore decreased cardiac output. However, hypervolemia can exacerbate RV pressure overload and ventricular interdependence, leading to decreased LV filling, also reducing cardiac output. Finding the optimal fluid balance for any given patient may require invasive hemodynamic monitoring.

Patients with RV dysfunction are poorly tolerant of loss of atrioventricular (AV) synchrony as occurs with atrial fibrillation and complete AV block. Therefore, maintenance of sinus rhythm may have salutary hemodynamic effects [33].

Retrospective and nonrandomized prospective studies of anticoagulation for patients with IPAH have demonstrated survival benefit with anticoagulation [34–36]. In the absence of contraindication, anticoagulation is therefore recommended for patients with PAH. However, there are no studies of anticoagulation for critically ill patients with pulmonary hypertension and thus no proven role for anticoagulation for this patient population.

Pulmonary Vasodilators

Significant advances in the outpatient treatment of PAH have been made since 1996 when the first pulmonary specific vasodilator was approved by the Food and Drug Administration (FDA). Patients with PAH (Group 1)
benefit from treatment with prostacyclins (epoprostenol, treprostinil, and iloprost), endothelin-receptor antagonists (bosentan, ambrisentan, and macitentan), phosphodiesterase-5 inhibitors (sildenafil and tadalafil), and the soluble guanylate cyclase stimulator (riociguat). Table 174.3 summarizes the major randomized controlled trials that have demonstrated clinical benefits with each of these medications [37]. Choice of initial therapy for stable outpatients with PAH is dictated by patients’ risk profile, as assessed by functional class, 6-minute walk distance, BNP level, hemodynamics, adverse events, and echocardiographic findings [38]. Oral pulmonary vasodilators are reserved for stable outpatients with low-risk profiles.

Patients with PAH and decompensated RV failure requiring admission to an ICU generally require treatment with intravenous prostanoids, although the initiation of pulmonary vasodilators as “rescue therapy” in the setting of decompensated right heart failure has not been well studied. In one small, retrospective study of patients with PAH and decompensated right heart failure, treatment with iloprost (inhaled) or treprostinil (intravenous or subcutaneous) was associated with decreased mortality [3]. However, in another study, treatment with intravenous epoprostenol or continuous iNO did not influence survival of patients with PAH or inoperable CTEPH and acute RV failure [4]. Of note, neither study was designed to study or compare the effects of pulmonary vasodilators on mortality from decompensated RV failure; therefore, no conclusions regarding which treatment may be most efficacious in this setting can be made.

Intravenous epoprostenol is the only medication with proven survival benefit in patients with IPAH [39] and is therefore the drug of choice for patients with severe PAH and a high-risk profile [40]. Epoprostenol therapy is typically initiated in the ICU with a right heart catheter in

6MWD, 6-min walk distance; WHO, World Health Organization.
place. It is started at a dose of 1 to 2 ng/kg/min and uptitrated by 1 to 2 ng/kg/min at intervals of 15 to 30 minutes, with the hemodynamic goal of increased cardiac output and decreased PAP and PVR. Dose escalation is limited by side effects, such as headache, jaw pain, nausea, diarrhea, and systemic hypotension [39].

Treatment with epoprostenol can be complicated by the development of pulmonary edema, due to increased delivery of blood to the left side of the heart with resultant increased left-sided filling pressures. The development of pulmonary edema following the initiation of epoprostenol therapy should prompt consideration of pulmonary veno-occlusive disease or pulmonary capillary hemangiomatosis, but this can also be seen with more common conditions such as occult diastolic dysfunction [41,42]. Epoprostenol results in nonselective pulmonary vasodilation. This can worsen V / O matching and cause clinically significant oxygen desaturation [43]. Among patients chronically treated with epoprostenol, this can cause severe hypoxemia if superimposed focal lung disease such as pneumonia occurs. Abrupt discontinuation of epoprostenol has been demonstrated to lead to severe rebound pulmonary hypertension and death.

Treatment of patients with non–Group 1 pulmonary hypertension is focused on treating the underlying disease. For patients with pulmonary venous hypertension, optimization of afterload reduction, and fluid management are the mainstays of therapy. Ensuring adequate oxygenation of patients with pulmonary hypertension due to parenchymal lung disease (Group 3) and treating the underlying disease are the main goals of therapy.

Given the frequent occurrence of pulmonary hypertension in patients with ARDS, much attention has been focused on treating this aspect of ARDS. Administration of intravenous and enteral pulmonary vasodilators to patients with ARDS and pulmonary hypertension increases intrapulmonary shunting with resultant deterioration in oxygenation without improving survival [8,44]. There is therefore no proven role for using these agents in patients with pulmonary hypertension related to ARDS.

Inhaled pulmonary vasodilators are only delivered to ventilated alveoli, and therefore improve V / Q matching and oxygenation for patients with ARDS, while reducing pulmonary pressures. Specifically, iNO improves oxygenation, reduces pulmonary shunting, and reduces PVR in patients with ARDS [45,46]. However, in two large, multicenter, randomized, controlled trials comparing treatment with iNO with conventional therapy for patients with ARDS, no mortality benefit was demonstrated [47,48]. Similarly, nebulized prostaglandin I2 improves oxygenation and decreases PAPs in patients with ARDS, without improving survival [49,50].
Vasopressors

Patients with pulmonary hypertension may develop hemodynamic instability requiring vasopressor support. This may be due to progression of pulmonary hypertension with the development of RV failure or due to the development of a superimposed process, such as sepsis. The main goals of vasopressor therapy for patients with pulmonary hypertension are to reduce PVR, preserve or improve cardiac output, and maintain systemic blood pressure. There are limited data to guide the choice of vasopressors in the setting of pulmonary hypertension and RV failure.

Dobutamine reduces PVR and increases cardiac output in animal models of pulmonary hypertension [14,51–53]. Among humans with mild-to-moderate pulmonary hypertension, dobutamine decreased PVR and increased CI; however, increased intrapulmonary shunting with resultant decrease in arterial oxygenation was also noted. Dobutamine administered in combination with iNO resulted in significant decreases of PVR with concomitant increases of CI and improved oxygenation [53,54]. Of note, these studies were performed in patients with stable cardiopulmonary hemodynamics. The physiologic effects of dobutamine for critically ill patients with pulmonary hypertension have not been well characterized. In a prospective, observational study of patients with PAH or inoperable CTEPH with acute RV failure requiring treatment with catecholamines, increasing dobutamine dose was associated with increased mortality [4]. However, this more likely reflects patients with more severe disease, rather than a deleterious effect of dobutamine on survival.

Norepinephrine administration for patients with pulmonary venous hypertension and systemic hypotension following induction of anaesthesia resulted in increased mPAP and PVR, but with decreased ratio of PAP to SBP (i.e., systolic blood pressure [SBP] increased more than PAP) and no change in CI. By contrast, phenylephrine administration resulted in decreased CI, without a concomitant decrease of the ratio of PAP to SBP [55]. Norepinephrine may be beneficial for restoring systemic blood pressure among patients with persistent hypotension despite treatment with pulmonary vasodilators and dobutamine, but should otherwise be avoided due to its pulmonary vasoconstrictive effects. Similarly, phenylephrine increases mPAP and PVR, with evidence of worsened RV function among patients with chronic pulmonary hypertension [56]. It should therefore be avoided for patients with hemodynamic compromise due to pulmonary hypertension.

Dopamine decreases PVR and increased cardiac output in an animal model.
model of acute pulmonary embolism [57]. Similar effects were noted in patients with pulmonary hypertension due to chronic obstructive lung disease [58]. Among humans with pulmonary venous hypertension, dopamine infusions increased mPAP, but this effect was mediated through increased cardiac output, not by pulmonary vasoconstriction [59]. The effects of dopamine among patients with PAH have not been well studied. In a retrospective, single-center study of patients with PAH and decompensated RV failure, higher doses of dopamine were associated with increased mortality. However, patients requiring treatment with dopamine had significantly more severe disease, by both clinical and hemodynamic parameters [3].

Vasopressin has been found to have vasodilatory properties at low doses in animal studies. Among humans, administration of low dose vasopressin has resulted in greater increases in SVR than in PVR, as manifest by a reduced PVR/SVR ratio. There are case reports describing successful use of vasopressin as rescue therapy for patients with pulmonary hypertension and acute hemodynamic instability in a variety of clinical contexts, including following cardiac surgery, with spinal anesthesia, during caesarean section, and during sepsis [25].

In an animal model of pulmonary hypertension, isoproterenol reduces PVR and improves cardiac output [57]. However, these beneficial effects are largely offset by induction of tachyarrhythmias [60]. Although isoproterenol reduces PVR among patients with IPAH, the chronotropic effects limit its role for patients with PAH [14].

There are limited studies of the effects of epinephrine on pulmonary hemodynamics. In hypoxic piglets, epinephrine improved cardiac output without increasing PVR, and resulted in improved RV contractility in a case series of patients with septic shock and RV failure [13].

Mechanical Ventilation

Institution of mechanical ventilation has complex hemodynamic effects that can be of clinical significance, especially among patients with severe PAH and decompensated RV failure.

Mechanical ventilation increases RV afterload and decreases RV preload that can be of particular hemodynamic consequence for patients with pulmonary hypertension. The increased afterload effects appear to be mediated primarily through increased lung volume [18]. Many of the studies evaluating effects of mechanical ventilation on RV function were performed prior to the era of low tidal volume ventilation for ARDS; therefore, it is unknown whether these effects are as pronounced or clinically important at lower tidal volumes.

Permissive hypercapnia has become common with the widespread institution of low tidal volume ventilation. Hypercapnia increases
pulmonary arterial pressures, although it is unclear whether this is due simply to increased cardiac output or by a direct pulmonary vasoconstrictive effect with one study demonstrating an increase in mPAP with no effect on PVR, while another has found an increase in mPAP, PVR, and decreased right ventricular ejection fraction (RVEF) [8]. Elevations of positive end-expiratory pressure (PEEP) also increase pulmonary arterial pressure and PVR [8]. In a recent study examining the hemodynamic effects of PEEP uptitration for patients with ARDS, mPAP increased from 25 to 28 mm Hg and PVR increased from 310 to 385 dynes s m² per cm⁵ [61].

In addition to providing a mortality benefit for patients with severe ARDS, prone positioning has been found to result in reduction of PaCO₂ and the improvement of echocardiographic findings of RV pressure overload [18]. Although the net effect of mechanical ventilation is to increase pulmonary arterial pressure, this is typically well tolerated among patients with mild-to-moderate pulmonary hypertension. These effects, however, may be of particular hemodynamic consequence for patients with PAH and RV failure. Mechanical ventilation in these patients should ideally be with low tidal volume and low PEEP, while avoiding permissive hypercapnia.

**Surgical Management**

Atrial septostomy, or the creation of an atrial septal shunt via graded balloon dilation atrial septostomy, decompresses the RV by creating an alternative outflow tract for blood and increases left atrial filling. However, it is associated with very high morbidity and mortality among critically ill patients with RV failure. It is complicated by oxygen desaturation through the creation of a right-to-left shunt. It is contraindicated for patients with mean RAP greater than 20 mm Hg and significant hypoxemia (O₂ saturation < 85% on room air at rest) [37].
REFERENCES

Hemoptysis is defined in Stedman’s Medical Dictionary as “the spitting of blood derived from the lungs or bronchial tubes.” This common symptom may be the primary reason for seeking consultation in approximately 8% to 15% of an average chest clinic population. It elicits great apprehension in the patient and is likely to prompt early medical attention. The basis for this fear is the presumption that the hemoptysis is caused by a serious disease (e.g., cancer) and that it signals impending massive bleeding. The patient may describe an associated burning pain, vague discomfort, or bubbling sensation in the chest and shortness of breath. Hemoptysis may be scant, producing the appearance of streaks of bright red blood in the sputum, or profuse, with expectoration of a large volume of blood.

Massive hemoptysis warrants prompt medical attention and should always be considered life threatening. It is poorly defined in the literature with volumes of expectorated blood ranging from 100 mL per 24 hours to 1,000 mL per 24 hours; however, the expectoration of 600 mL per 24 hours is what is most reported in the literature [1]. Despite the wide range of definitions and lack of clear consensus, the volumetric rate of bleeding does appear to correlate with mortality with those who expectorated 600 mL within 4 hours having a mortality of 70% or greater. In comparison, many clinicians now cite and prefer the magnitude of clinical effect definition that implies that the consequences of expectorated blood are more important than the absolute volume. Mortality in the setting of massive hemoptysis is typically related primarily to asphyxiation and not exsanguination. Asphyxiating hemoptysis occurs with bleeding rates in excess of 150 mL per hour leading to potential immediate airway occlusion. This is supported by the
knowledge that the average adult anatomical dead space of the tracheobronchial tree measures approximately 150 mL. Massive hemoptysis is estimated to occur in 5% to 15% of all patients with hemoptysis [2]. Nonmassive hemoptysis produces a quantity smaller than massive hemoptysis and greater than blood streaking. Dark red clots may also be expectorated when blood has been present in the lungs for days.

Pseudohemoptysis, on the other hand, is the expectoration of blood from a source other than the lower respiratory tract (below the larynx). It may cause diagnostic confusion when patients cannot clearly describe the source of their bleeding, which is not unusual. Pseudohemoptysis may occur when blood from the oral cavity, nares, pharynx, or tongue drains to the back of the throat and initiates the cough reflex; when blood emanating from the gastrointestinal tract is aspirated into the lower respiratory tract among patients who have hematemesis; and when the oropharynx is colonized with a red, pigment-producing, aerobic, gram-negative rod, *Serratia marcescens* [3]. Other rare causes of pseudohemoptysis are self-inflicted injuries, other bizarre tactics in the malingering patient seeking hospitalization (factitious hemoptysis), and rifampin overdose (red man syndrome) imbuing a reddish hue to secretions. The causes and distinguishing features of pseudohemoptysis are listed in Table 175.1.

This chapter deals with managing hemoptysis in the intensive care unit (ICU) in the context of a general discussion of hemoptysis. The management of tracheoarterial fistula, traumatic rupture of the pulmonary artery caused by balloon flotation catheters, and diffuse intrapulmonary hemorrhage or diffuse alveolar hemorrhage (DAH) are highlighted.
ETIOLOGY

Hemoptysis can be caused by a wide variety of disorders (Table 175.2) [4]. The etiology of hemoptysis is considered here in three general categories: nonmassive, massive, and idiopathic/cryptogenic. Patients in the ICU frequently have nonmassive hemoptysis, and the spectrum of the causes of hemoptysis for these patients probably differs little from that reported by major series. Commonly, the causes include trauma (secondary to suctioning), overzealous anticoagulation, and infection. Unlike the general ICU patient, patients with massive hemoptysis are frequently in the ICU because of their hemoptysis and thereby constitute a different subgroup of patients.

Nonmassive Hemoptysis

Although bronchiectasis, pneumonia, lung carcinoma, and tuberculosis have always been among the most common causes of hemoptysis, their incidence has varied depending on the study population, geographic location, and era. For example, among immunocompromised patients, *Pneumocystis jiroveci*, fungal diseases, *Mycobacterium tuberculosis*, and *Mycobacterium avium intracellulare* may be at the top of the differential diagnosis, and tuberculosis may be a more common cause of hemoptysis in China than in the USA [5,6]. Although bleeding from tracheoarterial fistula complicating tracheostomy; rupture of pulmonary artery from a balloon flotation catheter; and DAH may be submassive, they are discussed in the following section.

Massive Hemoptysis

The more frequent causes of massive hemoptysis likely to be seen in the ICU are listed in Table 175.3. Virtually, all causes of hemoptysis may result in massive hemoptysis, but it is most frequently caused by tuberculosis, bronchiectasis, infection, and lung cancer [2]. Infection is also a cause of bleeding from aspergilloma [7] or cystic fibrosis [8]. Hemoptysis due to cystic fibrosis has become more common because of the longer survival of affected patients [8]. Idiopathic or cryptogenic hemoptysis has been reported in 11% to 19% of patients despite extensive
diagnostic evaluation [2].

Rupture of a pulmonary artery complicates balloon flotation catheterizations in less than 0.2% of cases [9]. It is fortunate that it is uncommon because it carries a mortality rate of 40% to 70% [9–11]. With the less frequent use of this procedure, this complication has become uncommon and is now rarely seen. Tracheoarterial fistula is also an unusual but devastating condition, complicating approximately 0.7% of tracheostomies with a mortality rate exceeding 80% [12]. DAH, usually caused by an immunologically mediated disease, should also be considered in the differential diagnosis of massive hemoptysis in the ICU; however, 30% to 40% of patients may initially not present with hemoptysis and only diffuse pulmonary infiltrates on radiologic imaging.
Idiopathic Hemoptysis

Using the systematic diagnostic approach outlined later and in Tables 175.4 and 175.5, the cause of hemoptysis can be found in most instances. In 11% to 19% of patients [2], the cause cannot be determined. This condition, called idiopathic, cryptogenic or essential hemoptysis, is seen most commonly among men between the ages of 30 and 50 years. Prolonged follow-up studies with rare exceptions usually fail to reveal the source of bleeding, even though 10% of patients continue to have occasional episodes of hemoptysis [13]. In a subset of patients, Dieulafoy disease of the bronchus (i.e., an abnormal ectatic bronchial arterial superficial vessel contiguous to the epithelium of the bronchial mucosa) has been demonstrated at pathologic examination when surgery has been performed for massive bleeding and may be related to conditions associated with chronic airway inflammation [14].

PATHOGENESIS

To appreciate fully the pathogenesis of hemoptysis, it is necessary to review briefly the normal anatomy of the nutrient blood supply to the lungs. The bronchial arteries are the chief source of blood of the airways (from mainstem bronchi to terminal bronchioles); the supporting framework of the lung that includes the pleura, intrapulmonary lymphoid tissue; and large branches of the pulmonary vessels and nerves in the hilar regions. The pulmonary arteries supply the pulmonary parenchymal tissue, including the respiratory bronchioles. Communications between these two blood supplies, bronchopulmonary arterial and venous anastomoses, occur near the junction of the terminal and respiratory bronchioles. These anastomoses allow the two blood supplies to complement each other. Arteriographic studies of patients with active hemoptysis have shown that the systemic circulation (bronchial arteries) is primarily responsible for the bleeding in approximately 92% of cases [15]. When performing an exhaustive angiographic search for the cause of hemoptysis, one must always be suspicious for pulmonary arterial and nonbronchial systemic arterial collaterals as sources of hemoptysis when no clear bronchial arterial source is found.

The pathogenesis of hemoptysis depends on the type and location of the disease. In general, if the lesion is endobronchial, the bleeding is from the bronchial circulation, and if the lesion is parenchymal, the bleeding is from the pulmonary circulation. Moreover, for chronic diseases, repetitive episodes are most likely caused by increased vascularity at the involved area [4].

For bronchogenic carcinoma, hemoptysis results from necrosis of the tumor, with its increased blood supply from bronchial arteries, or from local invasion of a large blood vessel. For bronchial adenomas, bleeding is usually from rupture of the prominent surface vessels. For bronchiectasis, granulation tissue often replaces the normal bronchial wall and, with infection, this area can become irritated and bleed. In acute bronchitis, bleeding results from irritation of the unusually friable and vascular mucosa [4].

The mechanism of hemoptysis with mitral stenosis is controversial, but the most likely explanation is rupture of the dilated varices of the bronchial veins in the submucosa of large bronchi because of pulmonary venous hypertension [16]. Pulmonary venous hypertension may also be
responsible for the bleeding with congestive heart failure because it is associated with widening of the capillary anastomoses between bronchial and pulmonary arteries [17].

Hemoptysis from pulmonary embolism may be caused by infarction, with necrosis of parenchymal tissue, or caused by hemorrhagic consolidation secondary to increased bronchial artery blood flow that forms collaterals with the pulmonary circulation to bypass the obstructing clot [18].

With tuberculosis, bleeding can occur for a variety of reasons. In the acute parenchymal exudative lesion, scant hemoptysis may result from necrosis of a small branch of a pulmonary artery or vein. In the chronic parenchymal fibroulcerative lesion, massive hemoptysis may result from rupture of a pulmonary artery aneurysm bulging into the lumen of a cavity (Rasmussen’s aneurysm) [19,20]. The aneurysm occurs from tuberculous involvement of the adventitia and media of the vessel within or adjacent to a tuberculous cavity. When a healed and calcified tuberculous lymph node erodes the wall of a bronchus because of pressure necrosis, the patient may cough up blood as well as the calcified node (broncholith). With endobronchial tuberculosis, hemoptysis may result from acute tuberculous ulceration of the bronchial mucosa. With healed and fibrotic parenchymal areas of tuberculosis, bleeding may arise from irritation of granulation tissue in the walls of bronchiectatic airways in the same areas.

In traumatic rupture of the pulmonary artery by a balloon flotation catheter, risk factors include pulmonary hypertension, distal location of the catheter tip, excessive catheter manipulation in an attempt to obtain a pulmonary artery-occluded pressure measurement, a large catheter loop in the right ventricle, and advanced age [9–11].

In tracheoarterial fistula complicating tracheostomy, bleeding is caused by trauma from the tracheostomy cannula or balloon [12]. Bleeding usually is caused by the rupture of the innominate artery. The fistula can form at three tracheal locations: the stoma, the intratracheal cannula tip, and the balloon. Trauma at the stoma is caused by pressure necrosis, usually because the tracheostomy was created too low (below the fourth tracheal ring); at the cannula tip because of excessive angulation of the cannula; or at the balloon site because of pressure necrosis caused by use of excessive inflation pressures. Other risk factors include high cuff pressures, tubes that are malpositioned (too short and angulated) and stomal wound infections. These bleeds are devastating with mortality rates nearing 100% and typically occur 3 days to 6 weeks post-tracheostomy. They can reportedly be heralded by a sentinel bleed among 50% of cases in association occasionally with a pulsating tracheostomy tube. Because of this most-feared potential complication, it is recommended that any post-tracheotomy bleeding occurring 3 days to 6
weeks after insertion should be considered a tracheoarterial fistula until proven otherwise, requiring multimodality, vigilant approach with direct inspection, angiography, etc.

DAH associated with immunologic diseases is caused by an inflammatory lesion, usually of the capillaries [4].
DIAGNOSIS

General Considerations

The success rate for determining the cause of hemoptysis is excellent but variable. If one accepts the diagnosis of idiopathic (essential) hemoptysis as a distinct entity [14], the cause of hemoptysis can be determined in nearly 100% of cases [13]. The diagnostic work-up of hemoptysis involves routine (Table 175.4) as well as special evaluations (Table 175.5). Routine evaluations are initially performed for every patient, whereas special studies are ordered only when the clinical setting suggests that they are indicated. In general, each category of disease (Table 175.2) has its special studies (Table 175.5).

Routine Evaluation

As in any diagnostic problem, a detailed history and physical examination must be performed. These should be performed in a systematic fashion to rule in not only the common causes of hemoptysis but also the category of the cause (Table 175.2).

Although the amount of bleeding usually is not indicative of the seriousness of the underlying disease process, a history of the frequency, timing, and duration of hemoptysis may be helpful. For example, repeated episodes of hemoptysis occurring during months to years suggest a more chronic etiology such as bronchiectasis. Hemoptysis is typically a late finding in bronchogenic carcinoma although history may reveal small amounts of hemoptysis occurring every day for weeks. Hemoptysis that coincides with the menses (catamenial) suggests the rare diagnostic possibility of pulmonary endometriosis [21], whereas bleeding associated with sexual intercourse or other forms of exertion suggests passive congestion of the lungs [22].

Although hemoptysis may be a symptom at any age, it is distinctly uncommon in the young. When hemoptysis is present before the third decade of life, it suggests an acute tracheobronchitis, a congenital cardiac or lung defect, an unusual tumor, cystic fibrosis, a blood dyscrasia, trauma, or infectious pneumonia. No matter what the age, if a patient with pneumonia who is undergoing appropriate therapy has hemoptysis that persists for more than the usual 24 hours, an endobronchial lesion or coagulopathy should be suspected.

A travel history can often be helpful for bringing certain endemic diseases to mind. This is true of coccidioidomycosis and histoplasmosis in the USA; paragonimiasis and ascariasis in East Asia; and schistosomiasis
Chronic sputum production before hemoptysis suggests a diagnosis of chronic bronchitis, bronchiectasis, and cystic fibrosis. The presence of orthopnea and paroxysmal nocturnal dyspnea suggests the diagnoses of passive congestion of the lungs. A history of antithrombotic therapy suggests an intrapulmonary bleed due to supratherapeutic anticoagulation or possibly recurrent thrombotic disease if the anticoagulant is subtherapeutic or the patient is no longer anticoagulated. The possibility of pulmonary embolism should always be considered when a patient who presents with hemoptysis has been at an increased risk for deep venous thrombosis (e.g., meets Virchow’s triad).

The possibility of traumatic rupture of a pulmonary artery caused by balloon flotation catheterization should always be considered when these catheters are used [9–11].

Although tracheoarterial fistula must be considered in the differential diagnosis of hemoptysis in every patient with a tracheostomy, it is an infrequent cause in this setting. When it occurs, the onset is almost always at least 48 to 72 hours after the procedure [13]. Although the peak incidence is between the first and third week and 72% of fistulas bleed during the first 21 days after tracheostomy, hemorrhage from this complication can also occur as late as 18 months after the procedure [13]. There is a sentinel bleed in 34% to 50% of cases [12]. Before 48 hours, bleeding from the stoma is usually caused by capillary bleeding from inadequate hemostasis. Whenever hemoptysis occurs in a patient with an endotracheal tube or tracheostomy in place, trauma from suctioning should be considered, especially when coagulation is abnormal.

Although patients with DAH typically have hemoptysis, they occasionally do not expectorate at all but just complain of dyspnea, fever, cough, and malaise. Therefore, lack of hemoptysis does not rule out a substantial intrapulmonary hemorrhage because the alveoli can accommodate large volumes of blood [2].

The diagnosis of trimellitic anhydride–induced pulmonary hemorrhage should be suspected in workers exposed to high-dose trimellitic anhydride fumes. Exposure occurs when heated metal surfaces are sprayed with corrosion-resistant epoxy resin coatings. The syndrome requires a latent period of exposure and appears to be antibody mediated [23]. Respiratory failure with pulmonary infiltrates and hemoptysis has also been reported in a patient with a documented exposure and antibodies to isocyanates [24].

For a patient with the triad of known upper airway disease, lower
airway disease, and renal disease, antineutrophil cytoplasmic autoantibody (ANCA)—associated vasculitides, namely granulomatosis with polyangiitis (GPA)—formerly referred to as Wegener’s granulomatosis—should be suspected. Pulmonary hemorrhage can occur at any point during the course of the illness in the patient with systemic lupus erythematosus (SLE) and can also be the initial manifestation of the disease. Goodpasture’s syndrome (anti-glomerular basement membrane antibody mediated disease) typically occurs in young men and it has been reported to be associated with influenza infection, inhalation of hydrocarbons, and penicillamine ingestion. Therefore, it should be considered in these historical contexts [4].

DAH should be suspected for patients who have undergone recent hematopoietic stem cell transplantation when they present with cough, dyspnea, hypoxemia, and diffuse pulmonary infiltrates. This typically occurs with marrow recovery. It has been reported to occur in approximately 20% of patients during autologous bone marrow transplantation, and it has been associated with mortality rates of 64% to 100% [25–27]. Lung tissue injury, inflammation, and cytokine release are implicated in the pathogenesis of DAH of hematopoietic stem cell transplant patients.

Physical examination may be helpful in several ways. Inspection of the skin and mucous membranes may show telangiectasias, suggesting hereditary hemorrhagic telangiectasia, or ecchymoses and petechiae, suggesting a hematologic abnormality. Pulsations transmitted to a tracheostomy cannula should heighten suspicion, or risk, of a tracheoartery fistula. Inspection of the thorax may show evidence of recent or old chest trauma, and unilateral wheeze or rales may herald localized disease such as bronchial adenoma or carcinoma. Although pulmonary embolism is not definitively diagnosed on physical examination, tachypnea, phlebitis, and pleural friction rub suggest this disorder. If crackles are heard diffusely on chest examination, passive congestion as well as other diseases causing DAH should be considered (Table 175.2). Careful cardiovascular examination and echocardiography may identify mitral stenosis, pulmonary artery stenosis, or pulmonary hypertension.

The routine laboratory studies listed in Table 175.4 are useful for the following reasons.

The complete blood cell count results may suggest the presence of an infection, hematologic disorder, or chronic blood loss. Sputum should be sent for Gram stain and culture, including studies for acid-fast organisms. In addition, sputum should be sent for cytologic evaluation if the patient is a smoker and older than 40 years. Idiopathic hemosiderosis or other causes of DAH (Table 175.2) may present only with diffuse pulmonary infiltrates and iron deficiency anemia from chronic bleeding
into the lungs. Urinalysis may reveal hematuria and suggest the presence of a systemic disease associated with diffuse parenchymal disease (e.g., pulmonary renal hemorrhage syndrome due to SLE, Goodpasture’s syndrome, (ANCA)-associated vasculitides such as GPA and microscopic polyangiitis (MPA, and other systemic vasculitides; Table 175.2). Although there is simultaneous evidence of clinical involvement of the lungs and kidneys in 33% of cases of Goodpasture’s syndrome, there can be clinical lung involvement without renal disease and clinical renal involvement without lung disease.

Coagulation studies may uncover a hematologic disorder that is primarily responsible for the hemoptysis or that contributes to excessive bleeding from another disease. The electrocardiogram may help suggest the presence of a cardiovascular disorder. Although as many as 30% of patients with hemoptysis have negative chest radiographs [4], routine posteroanterior and lateral films may be diagnostically valuable. If unrevealing, one should strongly consider obtaining computed tomography (CT) of the chest not only for diagnosis, but when combined with intravenous contrast, modern multidetector CT angiography (MDCTA) of the chest can more accurately localize potential intrathoracic sources of the bleeding and provide a potential roadmap for subsequent interventions (e.g., bronchial arterial embolization [BAE]) [28,29].

When pulmonary tumor or infection is not readily apparent, there are other radiographic signs that may help to elucidate the cause and source of bleeding. Radiopaque foreign bodies may give rise to hemoptysis even years after entry into the lungs. One may note the disappearance of a calcified mediastinal lymph node after it has eroded the bronchial wall and is expectorated as a broncholith. Aortic or pulmonary aneurysms may erode into the bronchial tree. Single or multiple pulmonary cavities may suggest pulmonary tuberculosis, fungal disease, parasitic disease, acute or chronic lung abscess, neoplasm, septic pulmonary emboli, or GPA. The finding of a mass within a cavitary lesion raises the possibility of a fungus ball (aspergilloma), whereas localized honeycombing may be indicative of bronchiectasis. The presence of a new infiltrate localized to the area subtending a balloon flotation catheter suggests a rupture of the pulmonary artery [9–11]. The appearance of a new air-fluid level in a preexisting cavity or cyst suggests the location of the source of bleeding, as does a nonsegmental alveolar pattern that clears within a few days. A solitary pulmonary nodule with vessels going toward it suggests an arteriovenous fistula. Among patients with hemoptysis due to pulmonary embolism, a parenchymal density abutting a pleural surface with
evidence of pleural reaction or effusion is usually present. The cardiac silhouette, vascular or parenchymal patterns, and the presence of Kerley B lines may be useful in documenting cardiovascular disease.

When chest radiography shows diffuse pulmonary infiltrates, hemorrhage from bleeding disorders (e.g., thrombocytopenia in the compromised host), lung contusion from blunt chest trauma, freebase cocaine use, and passive congestion of the lungs should be considered, in addition to the diseases listed under “Diffuse Parenchymal Disease” in Table 175.2. In the earliest stages of DAH, chest radiographs may appear normal, but usually the hemorrhage first appears in a diffuse alveolar pattern. This progresses to a mixed alveolar–interstitial pattern and then, when bleeding ceases entirely, to an interstitial pattern, as hemosiderin deposition accumulates [25–27].

Bronchoscopy and Computed Tomography

Even if the history, physical examination, and chest radiograph are normal, or there is an “obvious” cause of hemoptysis on the chest radiograph, bronchoscopy is invaluable not only for accurate diagnosis but also for precise localization of the pulmonary hemorrhage. It is not uncommon for bronchoscopy to establish sites of bleeding different from those suggested by chest radiography. But not all patients with hemoptysis require bronchoscopy. Bronchoscopy may not be needed in patients with stable chronic bronchitis with one episode of blood streaking (especially those who are younger than 40 years of age with short-lived hemoptysis of less than 1 week duration where the likelihood of occult malignancy is low), particularly if associated with an exacerbation of acute tracheobronchitis, or in patients in whom the site of bleeding was recently documented by bronchoscopic examination. In addition, patients with acute lower respiratory tract infections, and patients with obvious cardiovascular causes of hemoptysis, such as congestive heart failure and pulmonary embolism, may not require bronchoscopic examination.

For localizing the bleeding site, the best results are obtained when bronchoscopy is performed during or within 24 hours of active bleeding. The bleeding site can be localized in up to 93% of patients with a flexible bronchoscope and in up to 86% with the rigid instrument [30,31]. When the procedure is done within 48 hours, localization of bleeding can drop to 51% [30,31]. When bronchoscopy is done after bleeding has ceased, accurate localization is likely to be reduced even further [30–32]. Although the flexible bronchoscope is usually the instrument of choice for diagnosing lower respiratory tract problems, rigid bronchoscopy is preferred in cases of massive, uncontrolled hemorrhage because patency of the airway is maintained more effectively during the procedure (see
Interventional Pulmonary Chapter 182). There are data that show that obtaining high-resolution chest CT scanning before bronchoscopy may enhance the yield of bronchoscopy [30–32]. With the exception of tracheoarterial fistula, the tracheobronchial disorders that can be diagnosed by a bronchoscopic examination are listed in Table 175.2.

Bedside bronchoscopy should not be performed to rule in the diagnosis of tracheoarterial fistula. In tracheostomized patients with hemoptysis, bronchoscopy should be performed to rule out other causes, such as bleeding from suction ulcers, tracheitis, or lower respiratory tract disorders. If no other cause for hemoptysis can be found and bleeding has stopped, or anterior and downward pressure on the cannula on the stomal site or overinflation of the tracheostomy balloon slows down or stops the bleeding, a surgical consultation (cardiothoracic and vascular) should be sought immediately and the patient brought to the operating room for examination in a more controlled environment. As long as tracheoarterial fistula remains a diagnostic possibility, the tracheostomy balloon should not be deflated, and the tracheostomy tube should not be removed without protecting the airway below the tracheostomy tube [12,33].

When there is no active bleeding, bronchoscopy with bronchoalveolar lavage can be helpful for diagnosing DAH. Return of bright red or progressively bloodier lavage fluid from multiple lobes (at least two segments) on serial lavage aliquots usually from both lungs suggests an active, DAH; lavage fluid containing more than 20% hemosiderin-laden macrophages (i.e., siderophages) on cytologic analysis from these same specimens suggest bleeding that has been ongoing and is also suggestive of DAH [34]. Because carbon monoxide–diffusing capacity is increased because of binding of carbon monoxide by intra-alveolar red blood cells for 24 to 48 hours after bleeding stops, this test may be helpful for suggesting intra-alveolar hemorrhage of the stable patient without hemoptysis but is rarely utilized currently.

In general, CT scanning plays an important role in the evaluation of hemoptysis and it has been shown by some studies to be as good as bronchoscopy for localizing the bleeding and superior to bronchoscopy at diagnosing the cause of bleeding [32]. Chest CT is superior to plain films and bronchoscopy in diagnosing bronchiectasis, tuberculous-related lesions, aspergillomas, and tumors, the most common causes of massive hemoptysis. CT, however, also has its limitations because it cannot provide direct visualization of the mucosa and associated abnormalities such as bronchitis, vascular anomalies including telangiectasias, early mucosal based carcinomas, benign papillomas and Kaposi’s sarcomas. Clearly for these cases, flexible bronchoscopy will be superior and bronchoscopy also provides the ability to additionally provide stabilizing, temporizing therapeutic interventions in some cases. Ultimately, CT scan
of the chest and flexible bronchoscopy should be essentially viewed as complementary to each other, and most clinicians would consider performing a CT scan without contrast on all cases of moderate to massive hemoptysis when feasible. As previously stated, the addition of IV contrast with performance of MDCTA can further enhance the ability of CT to further localize the source of bleeding particularly when one is planning on moving ahead with an interventional angiographic treatment modality to more precisely localize the anatomical circulatory source of the bleeding [35].

Angiography

Angiography can determine the site of bleeding in 90% to 93% of cases. When performed routinely, diagnostic angiography establishes a diagnosis not identified by bronchoscopy in only 4% of patients [15]. Although angiography may not be initially helpful in confirming the rupture of the pulmonary artery caused by balloon flotation catheterization if the rent has sealed, it can be extremely helpful for detecting a pseudoaneurysm that has formed during the healing process [10,11]. Identification of an unstable lesion is important because it should be obliterated to prevent future rupture and death [10,11]. Angiography has not been shown to be routinely useful for diagnosing tracheoarterial fistula and if the suspicion is high, one should proceed to direct inspection in the operating room with surgical consultant backup and involvement available [12,33]. Again, in recent years, MDCTA has gained popularity and become a key modality for the algorithmic approach to the diagnosis and management of massive hemoptysis at many institutions given its improved ability to localize the source of bleeding (bronchial arterial, pulmonary arterial, or nonbronchial systemic collaterals) with lower doses of contrast and provide valuable preplanning information to the interventional radiologist prior to embolization efforts [36].

Special Evaluation

Depending on the results of the initial evaluation and the possible categories of cause of hemoptysis (Table 175.2), additional diagnostic evaluations should be systematically performed (Table 175.5). The diagnosis of Goodpasture’s syndrome, for example, is made by demonstrating linear deposition of immunoglobulin (Ig) G along the basement membrane of the lung or kidney and the presence of high titers of circulating anti-glomerular basement membrane antibody in the
blood. Antibodies from patients with traditional Goodpasture’s syndrome react with the $\alpha_3$ (IV) chain of type IV collagen.

Definitive diagnosis of the pulmonary vasculitides depends on histologic examination, including special stains and cultures that rule out tuberculosis and fungal diseases. Pulmonary capillaritis with hemorrhage has been reported in an ever-increasing number of conditions [4,25–27]. The diagnosis can on rare occasion be made on transbronchial biopsy, thus avoiding the need for open or video-assisted thoracoscopic wedge lung biopsy [37], but care must be taken to exclude infectious etiologies by using special stains. Antineutrophil cytoplasmic autoantibodies are helpful for diagnosing GPA (formerly Wegener’s) and MPA and for potentially following disease activity [4,25–27]. The complete evaluation of GPA, MPA, SLE, and mixed cryoglobulinemia is reviewed in Chapters 66 and 67. The diagnostic features of polyarteritis nodosa, the hypersensitivity vasculitides, giant cell and Takayasu’s arteritis, and Behçet’s disease are also presented in detail in Chapter 67. For all of these, pulmonary involvement is rare. Several cases of Henoch–Schönlein syndrome, one of the hypersensitivity vasculitides, have been reported with severe alveolar hemorrhage, including one in which immunofluorescent stains of the lung revealed granular deposits of IgA consistent with an immune complex mediation. Giant cell arteritis involvement of the lung is suggested by upper respiratory tract symptoms of sore throat, cough, and hoarseness [4].

Although high levels of IgG, IgA, and IgM antibody to trimellitic-coupled protein and trimellitic-conjugated erythrocytes have been found among patients with trimellitic anhydride-induced pulmonary disease [23], the diagnosis can be made clinically by obtaining a history of the exposure and ruling out other diseases (Table 175.2).

It is important to be aware that diseases may be considered and therefore evaluated in more than one category. For instance, a patient with hemoptysis due to overzealous antithrombotic therapy may be evaluated in three categories: (a) a hematologic disorder that may cause, (b) localized, and (c) diffuse parenchymal disease. A patient with chronic bleeding from the tracheobronchial disorder of diffuse bronchial telangiectasis could present with diffuse as well as localized parenchymal disease (aspiration hemosiderosis). A patient with long-standing passive congestion of the lungs, a cardiovascular disorder, might present with diffuse pulmonary hemosiderosis, whereas a patient with acute pulmonary edema usually presents with diffuse pulmonary infiltrates.
DIFFERENTIAL DIAGNOSIS

When evaluating patients with hemoptysis, it is necessary to rule out the causes of pseudohemoptysis. Features that can help to differentiate the causes of pseudohemoptysis from one another and pseudohemoptysis from true hemoptysis are found in Table 175.1. In addition to history and routine physical examination, it is important to perform a meticulous examination of the nose and entire pharynx, preferably with a nasopharyngoscope. Unless the cause of pseudohemoptysis is definitively determined, the spitting up of blood must be assumed to be true hemoptysis until proven otherwise. An upper-airway lesion must not be assumed to be the cause of the bleeding unless it is seen bleeding actively at the time of examination. Not infrequently, the evaluation may require a team approach with the interprofessional involvement and input from a gastroenterologist and an otolaryngologist, as well as the primary evaluating pulmonary and/or critical care specialist.
TREATMENT

The treatment of hemoptysis can be divided into supportive and definitive categories. When prescribing definitive therapy, it is important to consider the cause, the amount and rate of bleeding, and the patient’s underlying lung function. The assessment and management of the patient is frequently occurring concurrently based on the pace and urgency of the overall presentation. The basic tenets of management include the following: (1) stabilization, (2) localization/lateralization, and (3) isolation and containment with potential definitive therapy.

Supportive Care

Supportive care usually includes bed rest and mild sedation. Drugs with antitussive effects (e.g., all narcotics) should not be used. An effective cough may be necessary to clear blood from the airways and avoid asphyxiation. Drugs with antiplatelet effects also should not be used and any underlying bleeding diathesis should be reversed when possible. Depending on the results of pulse oximetry or arterial blood gas analysis, supplemental oxygen should be given. If bleeding continues and gas exchange becomes further compromised, endotracheal intubation and mechanical ventilation may become necessary. To facilitate flexible bronchoscopy with a sufficiently large suction port, an endotracheal tube with an internal diameter of 8 mm or greater should be used, when possible. When the expertise is available at your facility, a strong consideration for moving directly to the operating room for rigid bronchoscopy should be strongly considered when the patient is actively bleeding, compromised, or at high risk for progressive decline. Other traumatic respiratory adjunctive therapies, such as chest physiotherapy and postural drainage, should be avoided. Fluid and blood product resuscitation as well as reversal agents for antithrombotic agents should be given when indicated.

The amount and rate of hemoptysis should be continuously monitored until bleeding stops. These parameters in addition to the patient’s clinical/functional status help determine the patient’s subsequent care. Current evolving management of massive hemoptysis focuses on an integrated, multipronged, and multidisciplinary approach to streamline efficient care and optimize outcomes [5].
Definitive Care

Nonmassive Hemoptysis

For patients with scant or frank (submassive) hemoptysis, treatment is directed at the specific cause. For instance, suppurative bronchiectasis is treated with antibiotics plus a mucociliary escalator drug (e.g., β-adrenergic agonists). Chronic bronchitis associated with cigarette smoking is treated with a mucociliary escalator and cessation of cigarette smoking. Broad-spectrum antibiotic therapy should be considered if hemoptysis occurs in the context of an acute exacerbation of chronic bronchitis. In severe exacerbations of ICU patients, gram-negative enteric rods, *Pseudomonas aeruginosa, Stenotrophomonas maltophilia*, and penicillin-resistant *Streptococcus pneumoniae* may be playing a role approximately 30% of the time [38]. Cystic fibrosis is treated with appropriate antibiotics to cover the likely pathogens [39], plus a mucociliary escalator. Bronchial adenoma and bronchogenic carcinoma should be resected whenever possible based on the patients underlying lung function and pulmonary reserves, when available. Recently, radiofrequency and microwave ablation has been used in stages III and IV non–small cell lung cancer for palliation of hemoptysis, cough, and pain, because reduction in tumor volume can lead to symptomatic improvement. However, hemoptysis has been reported as a complication of radiofrequency ablation in up to 12% of cases [40]. Congestive heart failure is treated with combinations of drugs for preload and afterload reductions, mitral stenosis with diuretics, and pulmonary embolism with anticoagulation. There are no data showing that patients with hemoptysis due to pulmonary embolism bleed more with anticoagulation; therefore, do not initially withhold treatment or undertreat these patients with nonmassive hemoptysis. The effects of overzealous anticoagulation are treated with cessation of blood thinning and perhaps fresh-frozen plasma and/or prothrombin complex concentrate and vitamin K. Tuberculosis is treated with antituberculous drugs (see Chapter 82). Appropriate antibiotic therapy is prescribed for acute infectious pneumonias (see Chapters 73 and 181).

Massive Hemoptysis

For patients with massive hemoptysis, treatment is directed not only at the specific cause but also at abrupt cessation of bleeding. Death from massive hemoptysis is predominantly because of asphyxiation, and the likelihood of death appears directly related to the rate of bleeding. Urgent management of all cases of massive hemoptysis must emphasize protecting the uninvolved lung from aspiration of blood and
tamponading the bleeding site.

When tracheoarterial fistula may be present, the following steps should be considered. If bleeding is immediate and profuse, there may be time only to overinflate the balloon, tamponading the potential bleeding site at the balloon, and apply downward and forward pressure on the top of the tracheostomy tube, tamponading the potential bleeding site at the stoma. When the arterial rupture is at the cannula tip, these efforts are not helpful. If bleeding stops or slows down either by these efforts or spontaneously, an endotracheal tube should be placed distal to the tip of the tracheostomy tube and a surgical consultation requested immediately. Ideally, a surgeon should be present when the tracheostomy tube is removed; should crisp bleeding start again, the surgeon can attempt to finger-tamponade/compress the bleeding artery (usually the innominate) by bluntly dissecting down the anterior tracheal wall and behind the sternum to the vessel. The vessel, once reached, can be compressed against the back of the sternum [12,33]. When the situation has been stabilized, clots can be gently suctioned from the distal trachea and the patient taken to the operating room for definitive repair. A review of the definitive surgical options can be found elsewhere [12,33]. There have also been reports recently of using the skills of interventional radiologists to place endovascular grafts in these acute settings to halt the bleeding from tracheoarterial fistulas but care must occur expeditiously to have any reasonable chance of survival [41].

When bleeding originates from below the primary carina, the bleeding lung should be kept dependent to minimize aspiration of expectorated blood (“bleeding side down”). Numerous techniques have been advocated to help minimize aspiration by isolating the involved lung or lung segments and have proved helpful. Simple, selective intubation of the uninvolved lung when possible and tolerable can be performed and augmented with bronchoscopic guidance. A bronchoscopically positioned endobronchial balloon or blocker may provide effective tamponade. Hemoptysis due to bleeding from all lobes except the right upper lobe, because of the acute angle takeoff, has been managed with balloon occlusion [2,42]. This technique involves positioning a balloon to completely occlude a bronchus, thus allowing the lung to collapse distally. Small-caliber catheters with balloons can be inserted in segmental airways with bronchoscopy. Placement of a double-lumen endotracheal tube that intubates each mainstem bronchus separately is helpful, but the tubes can be difficult to place and have a tendency to dislodge, and once in position, their small diameter may prevent subsequent diagnostic flexible bronchoscopy. In cases of persistent massive hemoptysis, diagnostic considerations may need to be delayed because placement of a double-lumen endotracheal tube may be necessary to ensure patient survival.
Urgent treatment to stop massive hemoptysis may involve laser bronchoscopy, argon plasma coagulation (APC)/electrocautery, installation of antifibrinolytic tranexamic acid, fibrinogen–thrombin complex solution installation, topically instilled epinephrine/vasoconstrictor solutions, iced saline lavage, angiographic embolization, supportive treatment only, or surgical resection. Use of laser or APC/electrocautery to stop hemoptysis can be successful for patients with cancer, but is only temporizing and recurrence of bleeding within a few weeks is typical. No large studies of patients with massive hemoptysis have been reported. Because “hot” therapies, such as laser, APC and electrocautery, are useful only for patients with proximal, central airway lesions and are difficult to use during massive hemoptysis, they have not evolved into a common primary therapeutic tools for these patients but do have a place in a multimodality approach in the face of an actively bleeding and decompensating patient.

Bronchoscopically directed iced-saline lavage of the bronchi leading to the site of hemorrhage has been reported to be successful for stopping hemorrhage in an uncontrolled series [2,42]. In addition, in a small number of patients, bronchoscopy-guided topical hemostatic therapy using oxidized regenerated cellulose has been successful in controlling life-threatening hemoptysis [43]. An excellent review of the overall contemporary bronchoscopic treatment strategies for massive hemoptysis can be found in the aforementioned references.

Angiography can identify the bleeding site in more than 90% of cases [15,44], and, when combined with an embolization procedure, has been successful in initially stopping bleeding in massive hemoptysis in 77% to 95% of cases [44]. Several angiographic sessions may be required, and systemic and pulmonary vessels may need to be studied. Approximately 16% of patients bleed again within 1 to 4 days, and multiple procedures are frequently necessary [15,44]. Once active bleeding ceases, 20% of patients bleed again during the next 6 months [44] and 22% of patients by 3 to 5 years [15]. More recent studies have shown similar results [44]. Angiographic embolization has been achieved with the use of polyurethane particles, polyvinyl alcohol particles, and steel coils. Sclerosing agents have led to subsequent massive lung necrosis and should be avoided [15,44]. Although early studies included several cases complicated by accidental embolization of the spinal artery, the prevalence is less than 1% and occurs when the spinal artery arises from the bronchial artery, an uncommon anatomical variant [44]. Other complications, such as pleurisy or hematoma formation, are infrequent.
and usually minor [15].

For patients with hemoptysis due to trauma, urgent thoracotomy has been advocated, with the recommendation that it is performed with the patient in the lateral decubitus position to minimize aspiration, and that the bronchovascular trunk of the involved lung is clamped while the patient is stabilized to minimize the chance of air embolism while on positive-pressure ventilation [45].

Survival from iatrogenic rupture of the pulmonary artery has been reported. Several urgent maneuvers may prove helpful, and balloon tamponade and selective intubation should always be attempted. Balloon tamponade of the ruptured vessel with the Swan–Ganz balloon has been helpful [46]. With the balloon deflated, the catheter should be withdrawn 5 cm and the balloon inflated with 2 mL of air and allowed to float back into the hemorrhaging vessel to occlude it. Ideally, patients should immediately be intubated in the mainstem bronchus opposite the involved lung to minimize aspiration. In most patients, death from pulmonary artery rupture occurs before the bleeding lung can be identified. Because the catheter usually floats to the right pulmonary artery, when it is not known which pulmonary artery has been ruptured, selective intubation of the left mainstem bronchus or placement of a double-lumen endotracheal tube should be attempted. Selective intubation of the left mainstem bronchus can be facilitated by using a bronchoscope or suction catheter designed specifically to enter the left lung. All patients who stop bleeding require angiographic evaluation to help localize the arterial tear and check for the formation of a pseudoaneurysm [11]. At the time of angiography, embolization of the affected vessel should be performed if a pseudoaneurysm or a tear is found. Hemoptysis from a pseudoaneurysm usually occurs in the first day after formation but may occur weeks later [10,11].

The role of emergency surgery for hemoptysis has changed during the past 20 years since the first report of bronchial artery embolization. Bronchial artery embolization has increasingly become first-line treatment for control of massive hemoptysis [5,44]. Nonetheless, surgery remains the procedure of choice when massive hemoptysis is caused by arteriovenous malformations, leaky aortic aneurysm, hydatid cyst, iatrogenic pulmonary rupture, chest trauma, bronchial adenoma, and fungal balls resistant to medical therapy [1].

In patients with cystic fibrosis, even with normal lung function, resection should be avoided because repeated episodes in other areas are likely to occur. A patient with a 1-second forced expiratory volume of less than 2 L or a maximum voluntary ventilation of less than 50% of predicted should not undergo surgery unless split-lung function studies reveal that the patient is not likely to be left a respiratory cripple because of disabling dyspnea.
With respect to surgery, it is clear that no treatment preference can be recommended for all patients on the basis of reported studies. The trials of therapy span different decades of practice, have widely differing causes of hemoptysis in their populations, and use several different definitions for massive hemoptysis. A review of the literature suggests the following strategy: (a) patients who are not candidates for surgery because of their pulmonary function, general medical condition, or diffuse nature of their lesions should be treated with selective embolization; (b) resectional surgery should be performed in operable patients when surgery is the definitive treatment for the underlying disease; and (c) all potentially operable patients who continue to bleed at rates of more than 1 L per day despite supportive, conservative care and subsequent embolization should undergo surgical resection. The correct therapy in a given patient depends on the cause of the bleeding, lung function, availability of resources, and local expertise.

For patients with DAH, selective arterial embolization and surgery are not options. Recombinant factor VIIa has been used successfully for treatment of DAH due to disseminated aspergillosis, bone marrow transplantation, small-vessel vasculitis, and cystic fibrosis [47,48]. For immunologically mediated diseases, corticosteroids, cytotoxic agents, and other interventions (e.g., plasmapheresis in Goodpasture’s syndrome) are available (see Chapters 67 and 68).

When corticosteroid therapy is given alone for critically ill patients with immunologic lung diseases, the dose is 1 mg/kg/d of intravenous methylprednisolone or the equivalent dose of another corticosteroid. Larger doses, on the order of 7 to 15 mg/kg/d for 1 to 3 days, have been recommended to control progressive pulmonary hemorrhage and hypoxemia of Goodpasture’s syndrome, SLE, and the vasculitides (see Chapters 66 and 67). In general, corticosteroids should be administered initially in round-the-clock divided doses until substantial improvement has occurred. They can then be given once per day and tapered as the patient’s condition dictates.

When combined corticosteroid and cytotoxic drug therapy is given, it is usually prescribed for immunologic lung diseases caused by vasculitides (e.g., GPA, MPA, and rheumatoid vasculitis) and anti-GBM disease (Goodpasture’s syndrome). For details regarding specific therapy for these conditions, see Chapters 66 and 67.

Pleural disease is an unusual cause for admission to the intensive care unit (ICU). Exceptions are a large hemothorax for monitoring bleeding rate and hemodynamic status and an unstable secondary spontaneous pneumothorax or large unilateral or bilateral pleural effusions that have caused acute respiratory failure.

Pleural disease can be overlooked among critically ill patients because it may be overshadowed by the presenting illness that has resulted in ICU admission. Furthermore, it is often a subtle finding on the clinical examination and supine chest radiograph. A pleural effusion may not be seen on the supine chest radiograph because a diffuse alveolar filling process can mask the posterior layering of fluid or because bilateral effusions without parenchymal infiltrates are misinterpreted as an underexposed film or objects outside the chest. Pneumothorax may remain undetected in the supine patient because pleural air tends to be situated anteriorly and does not produce the diagnostic visceral pleural line seen on an upright radiograph. However, it is clear that pleural ultrasound is a superior modality for the detection of pleural fluid and pneumothorax when compared to standard chest radiographs and is comparable to chest computed tomography (CT).

When the patient on mechanical ventilation is at increased risk for barotrauma because airway pressures are high, the index of suspicion for pneumothorax should be heightened; if there is evidence of pulmonary interstitial gas (see the following discussion) or subcutaneous emphysema, appropriate radiologic studies should be obtained.

RADIOLOGIC SIGNS OF PLEURAL DISEASE

Because the distribution of fluid and air in the normal pleural space tends
to follow gravitational influences, and because the lung has a tendency to maintain its normal shape as it becomes smaller, fluid initially accumulates between the bottom of the lung and the diaphragm, and air accumulates between the top of the lung and the apex of the thorax in the upright position. When chest radiographs are obtained in other than the erect position, free pleural fluid and air change position and result in a different radiographic appearance.
PLEURAL FLUID

Standard Chest Radiograph

In healthy humans in the supine position, the radiolucency of the lung base is equal to or greater than that in the lung apex [1]. Furthermore, when in the supine position, breast and pectoral tissue tend to fall laterally away from the lung base. Thus, an effusion should be suspected if there is increased homogeneous density over the lower lung fields compared to the upper lung fields. As the pleural effusion increases, the increased radiodensity involves the upper hemithorax as well. However, failure of chest wall tissue to move laterally, cardiomegaly, prominent epicardial fat pad, and lung collapse or consolidation may obscure a pleural effusion on a supine radiograph. Patient rotation or an off-center X-ray beam can mimic a unilateral homogeneous density. An absent pectoral muscle, prior mastectomy, unilateral hyperlucent lung, scoliosis, previous lobectomy, hypoplastic pulmonary artery, or pleural or chest wall mass may lead to unilateral homogeneous increased density and mimic an effusion.

Approximately 175 to 525 mL of pleural fluid results in blunting of the costophrenic angle on an erect radiograph. This quantity of effusion can be detected on a supine radiograph as an increased density over the lower lung zone. Failure to visualize the hemidiaphragm, absence of the costophrenic angle meniscus, and apical capping are less likely to be seen with effusions of less than 500 mL [1]. The major radiographic finding of a pleural effusion in a supine position is increased homogeneous density over the lower lung field that does not obliterate normal bronchovascular markings, does not show air bronchograms, and does not show hilar or mediastinal displacement until the effusion is massive. If a pleural effusion is suspected in the supine patient, ultrasonography (US) should be performed.

Other Radiographic Imaging

Ultrasonography

US provides rapid identification and characterization of pleural effusions for critically ill patients. US is well suited for the identification and evaluation of fluid, because fluid is less echogenic than soft tissue. Many studies have demonstrated the usefulness of ultrasound for this indication. Pleural effusions as small as 3 to 5 mL can be detected by ultrasound [1]. Pleural US is superior to standard chest radiography for
detecting the presence of pleural effusions and in distinguishing pleural effusions from atelectasis or pleural thickening \([2,3]\).

Compared to chest CT scan, pleural ultrasound has 93% sensitivity and specificity for pleural effusions \([4]\). More importantly, the complexity of the pleural effusion is better appreciated on ultrasound when compared to chest CT \([5]\).

(Fig. 176.1A–D)
FIGURE 176.1 A: An anechoic pleural effusion in a patient with decompensated congestive heart failure. B: A complex, nonseptate pleural effusion seen in a patient with malignant pleural effusion. C: A complex, septae pleural effusion seen in a patient with severe sepsis owing to the presence of an empyema. D: A complex pleural effusion with an anechoic area associated with an increased echogenic density in the dependent area of the fluid collection. This is called the “hematocrit sign” and occurred in a patient who developed a hemothorax as a result of extravascular migration of a central line into the pleural space.

US takes less time and is less expensive than CT, can be done at the
bedside, and can be repeated serially. Disadvantages include hindrance of the ultrasonic wave by air, in either the lung or the pleural space, a restricted field of view, inferior evaluation of the lung parenchyma compared with CT, and operator dependence. US was helpful for diagnosis among 27 (66%) of 41 patients and treatment of 37 (90%) of 41 patients, and had an important influence on treatment planning for 17 (41%) of 41 critically ill patients [4].

US has also been demonstrated to be a useful modality to guide bedside thoracentesis in the mechanically ventilated patient, resulting in high success rate and excellent safety of the procedure [6].

Free-flowing pleural effusions will layer posteriorly in the thorax of the supine patient. Patients with multiple lines or compromised hemodynamic and oxygenation status will be difficult to position sitting upright in bed. If the patient is supine, the bed may prevent the easy visualization of small pleural effusions. One option is for the examiner to place the transducer in the posterior axillary line while angling the probe up toward the center of the body to visualize smaller effusions. For unstable patients who have effusions that are difficult to visualize, positioning the patient in a lateral decubitus position may be helpful. The examiner should always use a systematic approach to identify the following three findings to confirm the presence of a pleural effusion (see Video 1-25 in Chapter 12 Cases).

1. Anatomic boundaries: An identification of the diaphragm and subdiaphragmatic organs (the liver or the spleen, depending on the side), the chest wall, and the lung, which should be clearly differentiated from the pleural effusion.

2. Echo-free space: The relatively echo-free space surrounded by typical anatomic boundaries is the pleural effusion.

3. Dynamic changes: Characteristic changes of the echo-free space should be identified.

These dynamic changes would be respirophasic change and lung flap. Another characteristic sign of pleural effusions is the plankton sign, which is caused by swirling debris agitated by cardiac or respiratory motion in a pleural effusion. Fibrin strands may be seen moving in synchronization with cardiac pulsations or respiratory motion. The hematocrit sign may be observed in cases of hemothorax or empyema. By gravitational effect, the effusion is layered into two phases of different echogenicity.

Debris, strands, or septations may be visible. In the case of parapneumonic effusions, these findings typically indicate the presence of a complicated parapneumonic effusion or an empyema [7].
Patients with septated effusions visible on US require longer hospital stays, longer chest tube drainage, and more often require fibrinolytic therapy or surgery for adequate drainage [8]. Pleural ultrasound is superior to CT scan for visualizing septations within a pleural effusion [9]. The identification and characterization of pleural fluid is discussed in detail in Chapter 12. In addition, the reader is referred to the video image library that is associated with this textbook that contains a comprehensive collection of US findings of pleural effusion.

**Computed Tomography**

CT is recognized as providing increased resolution compared with conventional imaging. Although moving a critically ill patient for CT has potential risks, the diagnostic advantage is justified for the stable patient when the clinical course is not congruent with the proposed diagnosis suggested by the portable chest radiograph or US. Among selected patients with multisystem trauma, chest CT often provides additional diagnostic information and positively affects patient management and outcomes.
PNEUMOTHORAX

When supine, pneumothorax gas migrates along the anterior surface of the lung, making detection on the anteroposterior radiograph problematic. The base, lateral chest wall, and juxtacardiac area should be carefully visualized for evidence of pneumothorax. Accumulation of air along the mediastinal parietal pleura may simulate pneumomediastinum. An erect or a decubitus (suspected hemithorax up) radiograph should be obtained to assess for the presence of a pneumothorax. US is sensitive for the detection of pneumothorax by determining the presence or absence of “lung sliding” [10]. Among individuals without pneumothorax, the lung–chest wall interface, which represents a to-and-fro movement synchronized with respiration, can be identified. US visualization of lung sliding is correlated with the absence of pneumothorax, and from this sign alone, at least anterior pneumothorax can be excluded rapidly at the bedside of a mechanically ventilated patient. However, the absence of lung sliding may be caused by the presence of large bullae or pleural symphysis caused by previous pleurodesis or pleural adhesions as a result of previous pleural disease. Hence, the absence of lung sliding is not specific for pneumothorax, but detection of lung sliding reliably excludes the presence of pleural air in the examined area. We recommend that preprocedural scanning be performed to determine the presence of lung sliding prior to the placement of a central venous line. The presence of lung sliding before and after the placement of a central venous catheter is reassuring for excluding an iatrogenic pneumothorax.

The most common radiographic signs of tension pneumothorax are contralateral mediastinal shift, ipsilateral diaphragmatic depression, and ipsilateral chest wall expansion. Underlying lung disease may prevent total lung collapse, even if tension is present; for patients on mechanical ventilation, little or no midline mediastinal shift may result from the tension. Among the latter, a depressed ipsilateral diaphragm is a more reliable sign of tension than mediastinal shift.

For patients with acute respiratory distress syndrome (ARDS), barotrauma can result in a localized tension pneumothorax with a subtle contralateral mediastinal shift, flattening of the cardiac contour, and depression of the ipsilateral hemidiaphragm [11]. Pleural adhesions and relative compressibility and mobility of surrounding structures, in addition to the supine position, probably account for these loculated
tension pneumothoraces.

A study of 88 critically ill patients with 112 pneumothoraces found that the anteromedial and subpulmonic recesses were involved for 64% of patients in the supine and semierect positions [12]. Furthermore, in 30% of the pneumothoraces of this study that were not initially detected by the clinician or radiologist, half of the patients progressed to tension pneumothorax. Therefore, a high index of suspicion is necessary to avoid catastrophic situations.

Factors that may contribute to an improved ability to diagnose this potentially lethal problem include (a) familiarity with atypical locations of pneumothoraces in critically ill patients, usually caused by the supine or semierect position; (b) the consequence of underlying cardiopulmonary disease; and (c) knowledge of other risk factors contributing to misdiagnosis (e.g., mechanical ventilation, altered mental status, prolonged ICU stay, and development of pneumothorax after peak physician staffing hours) [13].
EVALUATION OF THE PATIENT WITH A PLEURAL EFFUSION

Diagnostic Thoracentesis

Indications

Patients with a pleural effusion provide the opportunity to diagnose, at least presumptively, the underlying process responsible for pleural fluid accumulation. Pleural effusions are most commonly caused by primary lung disease but may also result from disease in the gastrointestinal tract, liver, kidney, heart, or reticuloendothelial system.

Although disease of any organ system can cause a pleural effusion in critically ill patients, the diagnoses listed in Table 176.1 represent the majority of the causes seen in ICUs. The types of pleural effusions seen in medical and surgical ICUs are similar, but some causes related to surgical (coronary artery bypass grafting, chylothorax, and abdominal surgery) and nonsurgical trauma (hemothorax) represent a substantial percentage of surgical ICU effusions.

ARDS, acute respiratory distress syndrome; ICU, intensive care unit.
When a pleural effusion is suspected on physical examination and confirmed radiologically, a diagnostic thoracentesis under ultrasonographic guidance should be performed in an attempt to establish the cause. Exceptions are patients with a secure clinical diagnosis and a small amount of pleural fluid, as in atelectasis, or patients with uncomplicated congestive heart failure (CHF) [14]. Observation may be warranted in these situations, but thoracentesis should be performed if there are adverse changes [15].

The indications for diagnostic thoracentesis do not change simply because the patient is in the ICU or on mechanical ventilation. In fact, establishing the diagnosis quickly for these critically ill patients may be more important and life-saving than in noncritically ill patients. It has been well documented that even among patients on mechanical ventilation, diagnostic thoracentesis is safe if there is strict adherence to the general principles of the procedure and US is used (see Chapter 12) [16]. Pneumothorax, the most clinically important complication of thoracentesis [11], is no more likely to occur during mechanical ventilation; however, when a pneumothorax does develop, the patient on mechanical ventilation is likely to develop a tension pneumothorax.

**Contraindications**

There are no absolute contraindications to diagnostic thoracentesis. If clinical judgment dictates that the information gained from the pleural fluid analysis may help in diagnosis and therapy, thoracentesis should be performed (see Chapter 12). Diagnostic thoracentesis with a small-bore needle can be performed safely in virtually any patient if meticulous technique is used. The major relative contraindications to thoracentesis are a bleeding diathesis or an anticoagulation. A patient with a small amount of pleural fluid and a low benefit to risk ratio also represents a relative contraindication. Thoracentesis should not be attempted through an area of active skin infection.

**Complications**

Complications of diagnostic thoracentesis include pain at the needle insertion site, bleeding (local, intrapleural, or intra-abdominal), pneumothorax, empyema, and spleen or liver puncture (see Chapter 12). Pneumothorax has been reported in prospective studies to occur in 4% to 30% of patients [17,18]. However, when ultrasound-guided thoracentesis is performed by experienced physician sonographers, pneumothorax or other injuries caused by organ puncture appear to be rare events. Liver or spleen puncture tends to occur when the patient is not sitting absolutely upright because movement toward recumbency causes cephalad
migration of the abdominal viscera. The upward displacement of abdominal organs is readily detected by US. However, even if the liver or the spleen is punctured with a small-bore needle, generally the outcome is favorable if the patient is not receiving anticoagulants and does not have a bleeding diathesis.

Therapeutic Thoracentesis

Indications and Contraindications

The primary indication for therapeutic thoracentesis is relief of dyspnea. Contraindications to therapeutic thoracentesis are similar to those for diagnostic thoracentesis. However, there appears to be an increased risk of pneumothorax, thus making a therapeutic thoracentesis in patients on mechanical ventilation potentially hazardous.

The technique for therapeutic thoracentesis is essentially the same as for diagnostic thoracentesis, except that a blunt-tip needle or plastic catheter, rather than a sharp-tip needle, should be used (see Chapter 12). This reduces the risk of pneumothorax, which may occur because fluid is removed and the lung expands toward the chest wall. Again, the use of sonographic guidance is recommended.

The amount of fluid that can be removed safely from the pleural space at one session is controversial. Ideally, monitoring pleural pressure should dictate the amount of fluid that can be removed. As long as intrapleural pressure does not fall to less than $-20$ cm H$_2$O, fluid removal can continue [19]. However, intrapleural pressure monitoring is not done routinely. In the patient with contralateral mediastinal shift on chest radiograph who tolerates thoracentesis without chest tightness, cough, or light-headedness, probably several liters of pleural fluid can be removed safely. However, neither the patient nor the operator may be aware of a precipitous drop in pleural pressure. In patients without a contralateral mediastinal shift or with ipsilateral shift (suggesting an endobronchial obstruction), the likelihood of a precipitous drop in intrapleural pressure is increased, and pleural pressure should be monitored during thoracentesis. Alternatively, a small-bore catheter connected to a standard thoracostomy pleural drainage system may be temporarily inserted, thus avoiding excessively negative pleural pressure development during drainage. Simple gravity drainage or drainage using any system incorporating a nonreturn valve does not reliably guard against the development of excessively negative pressure.
Physiological Effects and Complications

Improvement in lung volumes up to 24 hours after therapeutic thoracentesis does not correlate with the amount of fluid removed, despite relief of dyspnea in those patients [20]. In some patients, however, maximum spirometric improvement may not occur for several days. Patients with initial negative pleural pressures and those with more precipitous falls in pleural pressure with thoracentesis tend to have the least improvement in pulmonary function after therapeutic thoracentesis because many have a trapped lung or an endobronchial obstruction [18]. The mechanism of dyspnea from a large pleural effusion probably is related to the increase in chest wall resting volume resulting in shortening of the respiratory muscles resting length and consequent decrease in contractile efficiency [21]. Drainage of moderately sized pleural effusions (1,495 mL) does not appear to result in predictable changes of respiratory system compliance or resistances although a systematic decrease of work performed by the ventilator as a consequence of thoracentesis has been reported [22].

Complications of therapeutic thoracentesis are the same as those seen with diagnostic thoracentesis (see Chapter 12). Three complications that are unique to therapeutic thoracentesis are hypoxemia, unilateral pulmonary edema, and hypovolemia. After therapeutic thoracentesis, hypoxemia may occur despite relief of dyspnea [23,24] from worsening ventilation–perfusion relationships in the ipsilateral lung or clinically occult unilateral pulmonary edema.

Some investigators have concluded that the change in partial pressure of arterial oxygen (PaO₂) after therapeutic thoracentesis is unpredictable [24]; some have observed a characteristic increase in PaO₂ within minutes to hours [19], whereas others suggest a systematic decrease in PaO₂ that returns to prethoracentesis values by 24 hours [23]. In the largest study, including 33 patients with various causes of unilateral pleural effusions, a significant increase of PaO₂ was found 20 minutes, 2 hours, and 24 hours after therapeutic thoracentesis [25]. This was in conjunction with a decrease in the alveolar–arterial oxygen gradient [P(A–a)O₂] and was accompanied by a small but significant decrease in shunt, without a change in V_D/V_T. Data suggest an improved ventilation–perfusion relationship after therapeutic thoracentesis, with an increase in ventilation of parts of the lung that were previously poorly ventilated but well perfused. The relief of dyspnea among these patients cannot be explained by improved arterial oxygen tension. The increases have been modest, and, in some cases, there has been a fall in PaO₂. Improvement in lung volumes is a constant finding after therapeutic thoracentesis but
may take days or even weeks to maximize; immediate changes are usually modest and highly variable. Therefore, the relief of dyspnea cannot be adequately explained by changes in lung volume or in the mechanics of breathing but may be the result of decreased stimulation of lung or chest wall receptors, or both [20].
PLEURAL EFFUSIONS OF THE CRITICALLY ILL

The types of pleural effusions in critically ill patients are listed in Table 176.2.

**Atelectasis**

Atelectasis is a common cause of small pleural effusions among comatose, immobile, pain-ridden patients in ICUs [26] and after upper abdominal surgery [27]. Other causes include major bronchial obstruction from lung cancer or a mucous plug. Atelectasis causes pleural fluid because of decreased pleural pressure. With alveolar collapse, the lung and chest wall separate further, creating local areas of increased
negative pressure. This decrease of pleural pressure favors the movement of fluid into the pleural space, presumably from the parietal pleural surface. The fluid accumulates until the pleural or parietal-pleural interstitial pressure gradient reaches a steady state.

Pleural fluid from atelectasis is a serous transudate with a low number of mononuclear cells, a glucose concentration equivalent to serum, and pH in the range of 7.45 to 7.55. When atelectasis resolves, pleural fluid dissipates during several days.

Congestive Heart Failure

CHF is the most common cause of transudative pleural effusions and a common cause of pleural effusions among the critically ill. Pleural effusions as a result of CHF are associated with increases of pulmonary venous pressure [28]. Most patients with subacute or chronic elevation of pulmonary venous pressure (pulmonary capillary wedge pressure of at least 24 mm Hg) have evidence of pleural effusion on US or lateral decubitus radiograph. Isolated increases in systemic venous pressure tend not to produce pleural effusions. Thus, patients with chronic obstructive pulmonary disease (COPD) and cor pulmonale rarely have pleural effusions, and the presence of pleural fluid implies another cause.

Most patients with pleural effusions secondary to CHF have the classic signs and symptoms. The chest radiograph shows cardiomegaly and bilateral small-to-moderate pleural effusions of similar size (right slightly greater than left). There is usually radiographic evidence of pulmonary congestion, with the severity of pulmonary edema correlating with the presence of pleural effusion.

The effusion is a transudate, with mesothelial cells and lymphocytes accounting for the majority of the less than 1,000 cells per μL. Acute diuresis can raise the pleural fluid protein and lactate dehydrogenase into the range of an exudate [29,30]. In the patient with secure clinical diagnosis of CHF, observation is appropriate. Thoracentesis should be performed if the patient is febrile, has pleural effusions of disparate size, has a unilateral pleural effusion, does not have cardiomegaly, has pleuritic chest pain, or has a PaO₂ inappropriate for the degree of pulmonary edema.

Treatment consists of decreasing pulmonary venous hypertension and improving cardiac output with diuretics, ionoropes, or afterload reduction. In successfully managed heart failure, the effusions resolve during days to weeks after the pulmonary edema has cleared.

Hepatic Hydrothorax

Pleural effusions occur in approximately 6% of patients with cirrhosis of
the liver and clinical ascites. The effusions result from movement of ascitic fluid through congenital or acquired diaphragmatic defects [31].

The patient usually has the classic stigmata of cirrhosis and clinically apparent ascites. The usual chest radiograph shows a normal cardiac silhouette and a right-sided pleural effusion, which can vary from small to massive; effusions are less likely isolated to the left pleural space or are bilateral [31]. Rarely, a massive pleural effusion may be found without clinical ascites (demonstrated only by US), implying the presence of a large diaphragmatic defect. The pleural fluid is a serous transudate with a low nucleated cell count and a predominance of mononuclear cells, pH greater than 7.40, and a glucose level similar to that of serum. The fluid can be hemorrhagic owing to an underlying coagulopathy or rupture of a diaphragmatic bleb. Demonstrating that pleural and ascitic fluids have similar protein and lactate dehydrogenase concentrations, substantiates the diagnosis. If diagnosis is problematic, injection of a radionuclide into the ascitic fluid with detection on chest imaging within 1 to 2 hours supports a pleuropertitoneal communication through a diaphragmatic defect [32]; delayed demonstration of the tracer suggests that the pathogenesis of the effusion is via convection through the mesothelium.

Hepatic hydrothorax may be complicated by spontaneous bacterial empyema (SBE), which is analogous to spontaneous bacterial peritonitis. The criteria for diagnosis of SBE are similar to those for the diagnosis of spontaneous bacterial peritonitis. SBE must be considered in the differential diagnosis of the infected cirrhotic patient, even in the absence of clinical ascites [33,34]. The pleural fluid culture and analysis may reveal positive culture, a total neutrophil count of more than 500 cells per μL, and a serum to pleural fluid albumin gradient greater than 1.1. The chest radiograph should not show a pneumonic process. Treatment of SBE is conservative with antibiotics unless purulence is present, in which case tube thoracostomy must be considered.

Treatment of hepatic hydrothorax is directed at resolution of the ascites, using sodium restriction and diuresis. The effusion frequently persists unchanged until all ascites is mobilized. If the patient is acutely dyspneic or in respiratory failure, therapeutic thoracentesis should be done as a temporizing measure. Care should be exercised with paracentesis or thoracentesis because hypovolemia can occur with rapid evacuation of fluid. Chest tube insertion should be avoided because it can cause infection of the fluid, and prolonged drainage can lead to protein and lymphocyte depletion and renal failure. Chemical pleurodesis via a chest tube is often unsuccessful owing to rapid movement of ascitic fluid
into the pleural space. Treatment options in hepatic hydrothorax refractory to medical management include transjugular intrahepatic portal systemic shunt and video-assisted thoracoscopy to patch the diaphragmatic defect, followed by pleural abrasion or talc poudrage for the properly selected patient [35,36].

**Hypoalbuminemia**

Many patients admitted to a medical ICU have a chronic illness and associated hypoalbuminemia. When the serum albumin level falls below 1.8 g per dL, pleural effusions may be observed [37]. Because the normal pleural space has an effective lymphatic drainage system, pleural fluid tends to be the last collection of extravascular fluid that occurs in patients with low oncotic pressure. Therefore, it is unusual to find a pleural effusion solely because of hypoalbuminemia in the absence of anasarca. Patients with hypoalbuminemic pleural effusions tend not to have pulmonary symptoms unless there is underlying lung disease, because the effusions are rarely large. Chest radiograph shows small-to-moderate bilateral effusions and a normal heart size. The pleural fluid is a serous transudate with less than 1,000 nucleated cells per μL, predominantly lymphocytes and mesothelial cells. The pleural fluid glucose level is similar to that of serum, and the pH is in the range of 7.45 to 7.55. Diagnosis is presumptive if other causes of transudative effusions can be excluded. The effusions resolve when hypoalbuminemia is corrected.

**Iatrogenic**

Extravascular migration of a central venous catheter can cause pneumothorax, hemothorax, chylothorax, or a transudative pleural effusion [38,39]. Its incidence is estimated at less than 1% but may be considerably higher. Malposition of the catheter on placement should be suspected if there is absence of blood return or questionable central venous pressure measurements. The immediate postprocedure chest radiograph should be assessed for proper catheter placement; a catheter placed from the right side should not cross the midline. If the catheter is not in the appropriate vessel, phlebitis, perforation of a vein or the heart, or instillation of fluid into the mediastinum or pleural space can occur. In the alert patient, acute infusion of intravenous fluid into the mediastinum usually results in new-onset chest discomfort and dyspnea. Depending on the volume and the rate at which it is introduced into the mediastinum, tachypnea, worsening respiratory status, and cardiac tamponade may ensue. The chest radiograph shows the catheter tip in an abnormal position [40,41], a widened mediastinum, and evidence of unilateral or bilateral pleural effusions. The effusion can have characteristics similar to those of the infusate (milky if lipid is being given) and may be
hemorrhagic and neutrophil predominant as a result of trauma and inflammation. The pleural fluid to serum glucose ratio is greater than 1.0 if glucose is being infused [39]. The pleural fluid glucose concentration can fall rapidly after glucose infusion into the pleural space, probably explaining the relatively low glucose concentrations of pleural fluid compared to the infusate. Extravascular migration of a central venous catheter appears to be more common with placement in the external jugular vein, particularly on the left side. Left-sided catheters appear to put the patient at increased risk of perforation because of the horizontal orientation of the left brachiocephalic vein compared to the right brachiocephalic vein. When catheters are introduced from the left side, they should be of adequate length for the tip to rest in the superior vena cava.

Free flow of fluid and proper fluctuation of central venous pressure during the respiratory cycle may not be reliable indicators of intravascular placement. This is probably because intrathoracic pressure changes are transmitted to the mediastinum and, thus, the venous pressure catheter. Aspiration of blood or retrograde flow of blood when the catheter is lowered below the patient’s heart level should confirm intravascular catheter placement. If blood cannot be aspirated and the effusate is aspirated instead, extravascular migration is assured. The central venous catheter should be removed immediately. If there is a small effusion, observation is warranted. If the effusion is large, causing respiratory distress, or a hemothorax is discovered, thoracentesis or tube thoracostomy should be performed.

Parapneumonic Effusions

Community-acquired or nosocomial pneumonia is common among critically ill patients. The classic presentation is fever, chest pain, leukocytosis, purulent sputum, and a new alveolar infiltrate on chest radiograph. For the elderly, debilitated patient, however, many of these findings may not be present. The chest radiograph commonly shows a small-to-large ipsilateral pleural effusion [42]. When the effusion is free flowing and anechoic on ultrasound, and thoracentesis shows a nonpurulent, polymorphonuclear (PMN) predominant exudate with a pH of 7.30 or greater, it is highly likely that the effusion will resolve during 7 to 14 days without sequelae with antibiotics alone (uncomplicated effusion). If the chest radiograph or CT demonstrates loculation and pus is aspirated, the diagnosis of empyema is established, and immediate drainage is needed. In the free-flowing nonpurulent fluid, if Gram’s stain or culture is positive or pH is less than 7.30, the likelihood of a poor outcome increases, and the pleural space should be drained.
Although a meta-analysis found that low-risk patients with fluid pH between 7.20 and 7.30 may be managed without tube drainage, the patient admitted to the ICU typically cannot be considered low risk, and pH values of less than 7.30 should prompt drainage in most cases [43–45]. Drainage can be accomplished by standard chest tube or small-bore catheter. When loculations occur, pleural space drainage should be accomplished by placement of image-guided tubes or catheters with fibrinolytics plus DNase or empyectomy and decortication [46–48]. Most thoracic surgeons routinely begin with thoracoscopy and, if not successful, proceed directly to a standard thoracotomy for empyectomy and decortication [49–52].

Pancreatitis

Pleuropulmonary abnormalities are commonly associated with pancreatitis, largely because of the close proximity of the pancreas to the diaphragm. Approximately half of patients with pancreatitis have an abnormal chest radiograph, with pleural effusions in 3% to 17% [53,54]. Mechanisms that may be involved in the pathogenesis of pancreatic pleural effusion include (a) direct contact of pancreatic enzymes with the diaphragm (sympathetic effusion), (b) transfer of ascitic fluid via diaphragmatic defects, (c) communication of a fistulous tract between a pseudocyst and the pleural space, and (d) retroperitoneal movement of fluid into the mediastinum with mediastinitis or rupture into the pleural space [53,54]. Ascitic amylase moves into the pleural space via the previously mentioned mechanisms. The pleural fluid to serum amylase ratio is greater than unity in pancreatitis because of slower lymphatic clearance from the pleural space compared with more rapid renal clearance.

The effusion associated with acute pancreatitis is usually small and left sided (60%), but may be isolated to the right side (30%) or be bilateral (10%). The patient usually presents with abdominal symptoms of acute pancreatitis. The diagnosis is confirmed by an elevated pleural fluid amylase concentration that is greater than that of serum. A normal pleural fluid amylase may be found early in acute pancreatitis, but increases on serial measurements. The fluid is a PMN-predominant exudate with glucose values approximating those of serum. Leukocyte counts may reach 50,000 cells per μL. The pleural fluid pH is usually 7.30 to 7.35 [54].

No specific treatment is necessary for the pleural effusion of acute pancreatitis; the effusion resolves as the pancreatic inflammation subsides. Drainage of the pleural space does not appear to affect residual
pleural damage. If the pleural effusion does not resolve in 2 to 3 weeks, pancreatic abscess or pseudocyst should be excluded.

**Pulmonary Embolism**

The presence of a unilateral pleural effusion may suggest pulmonary embolism or obscure the diagnosis by directing attention to a primary lung or cardiac process. Pleural effusions occur in approximately 40% of patients with pulmonary embolism [54,55]. These effusions result from several different mechanisms, including increased pleural capillary permeability, imbalance in microvascular and pleural space hydrostatic pressures, and pleuropulmonary hemorrhage ischemia from pulmonary vascular obstruction, in addition to release of inflammatory mediators from platelet-rich thrombi, can cause capillary leak into the lung and, subsequently, the pleural space, explaining the usual finding of an exudative effusion. Transudates, described in approximately 20% of patients with pulmonary embolism, result from atelectasis [54].

With pulmonary infarction, necrosis and hemorrhage into the lung and pleural space may result. More than 80% of patients with infarction have bloody pleural effusions, but more than 35% of patients with pulmonary embolism without radiographic infarction also have hemorrhagic fluid [55]. The presence of a pleural effusion does not materially alter the signs or symptoms for patients with pulmonary embolism. Chest pain, usually pleuritic, occurs among most patients with pleural effusions complicating pulmonary embolism, and is invariably ipsilateral [56]. The chest radiograph virtually always shows a unilateral effusion that occupies less than one-third of the hemithorax. An associated pulmonary infiltrate (infarction) is seen in approximately half of patients with pulmonary embolism and effusion.

Pleural fluid analysis is variable and nondiagnostic [54]. The pleural fluid is hemorrhagic in two-thirds of patients, but the number of red blood cells exceeds 100,000 per μL in less than 20% [57]. The nucleated cell count ranges from less than 100 (atelectatic transudates) to greater than 50,000 per μL (pulmonary infarction) [54]. There is a predominance of PMNs when a thoracentesis is performed near the time of the acute injury and of lymphocytes with later thoracentesis. The effusion as a result of pulmonary embolism is usually (92%) apparent on the initial chest radiograph and reaches a maximum volume during the first 72 hours. Patients with pleural effusions that progress with therapy should be evaluated for recurrent embolism, hemothorax secondary to anticoagulation, an infected infarction, or an alternate diagnosis. When consolidation is absent on chest radiograph, effusions usually resolve in 7 to 10 days; with consolidation, the resolution time is 2 to 3 weeks [54].

The association of pleural effusion with pulmonary embolism does not
alter therapy. Furthermore, the presence of a bloody effusion is not a contraindication to full-dose anticoagulation because hemothorax is a rare complication of heparin therapy. An enlarging pleural effusion on therapy necessitates thoracentesis to exclude hemothorax, empyema, or another cause. Active pleural space hemorrhage necessitates discontinuation of anticoagulation, tube thoracostomy, and placement of a vena cava filter.

**Postcardiac Injury Syndrome**

Postcardiac injury syndrome (PCIS) is characterized by fever, pleuropericarditis, and parenchymal infiltrates 3 weeks (2 to 86 days) after injury to the myocardium or pericardium [58–61]. PCIS has been described after myocardial infarction, cardiac surgery, blunt chest trauma, percutaneous left ventricular puncture, and pacemaker implantation. The incidence after myocardial infarction has been estimated at up to 4% of cases [58], but with more extensive myocardial and pericardial involvement, it may be higher. It occurs with greater frequency (up to 30%) after cardiac surgery [60]. The pathogenesis of PCIS remains obscure but is probably on an autoimmune basis in patients with myocardial or pericardial injury and, possibly, concomitant viral illness [61].

The diagnosis of PCIS remains one of exclusion, for no specific criteria exist. It is important to diagnose or exclude PCIS presumptively. Failure to diagnose accurately could lead to iatrogenic complications from inappropriate therapy, such as cardiac tamponade from anticoagulation for presumed pulmonary embolism and adverse effects related to antimicrobial therapy for presumed pneumonia.

Pleuropulmonary manifestations are the hallmark of PCIS. The most common presenting symptoms are pleuritic chest pain, found in virtually all patients, and fever, pericardial rub, dyspnea, and rales, which occur in half of patients [59]. Rarely, hemoptyis occurs, an important differential point when pulmonary embolism with infarction is in the differential diagnosis. Fifty percent of patients have leukocytosis, and almost all have an elevated erythrocyte sedimentation rate (average, 62 mm per hour) [59].

The chest radiograph is abnormal among virtually all patients, with the most common abnormality being left-sided and bilateral pleural effusions; a unilateral right effusion is unusual [59]. Pulmonary infiltrates are present in 75% of patients and are most commonly seen in the left lower lobe [58]. The pleural fluid is a serosanguineous or bloody exudate with a glucose level greater than 60 mg per dL and pleural fluid pH greater than 7.30. Nucleated cell counts range from 500 to 39,000 per μL, with a predominance of PMNs early in the course [59].
Pericardial fluid on echocardiogram is an important finding suggesting PCIS. The pleural fluid characteristics should help differentiate PCIS from a parapneumonic effusion and CHF, but do not exclude pulmonary embolism.

PCIS is usually self-limited and may not require therapy if symptoms are trivial. It usually responds to aspirin or nonsteroidal anti-inflammatory agents, but some patients require corticosteroid therapy for resolution. In those who respond, the pleural effusion resolves within 1 to 3 weeks.

Esophageal Sclerotherapy

Pleural effusions are found in approximately 50% of patients 48 to 72 hours after esophageal sclerotherapy with sodium morrhuate and in 19% of patients after absolute alcohol sclerotherapy [62–64]. Effusions may be unilateral or bilateral, with no predilection for side. Effusion appears more likely with larger total volumes of sclerosant injected and larger volume injected per site [62,63]. The effusions tend to be small, serous exudates with variable nucleated (90 to 38,000 per μL) and red cell counts (126 to 160,000 per μL) and glucose concentration similar to that of serum [62]. These effusions probably result from an intensive inflammatory reaction after extravasation of the sclerosant into the esophageal mucosa, resulting in mediastinal and pleural inflammation. The effusion is not associated with fever, chest pain, or evidence of perforation is of little consequence, requires no specific therapy, and resolves during several days to weeks [62,63]. However, late perforation may evolve among patients with apparent innocuous effusions. For patients with symptomatic effusions for 24 to 48 hours, diagnostic thoracentesis should be done and an esophagram considered.

Acute Respiratory Distress Syndrome

The presence of pleural effusions in ARDS has not been well appreciated. In a retrospective study of 25 patients with ARDS, a 36% incidence of pleural effusions was found, a percentage similar to that found with hydrostatic pulmonary edema [56]. All patients had extensive alveolar pulmonary edema and endotracheal tube fluid that was compatible with increased permeability edema. Several experimental models of increased permeability pulmonary edema, including α-naphthyl thiourea, oleic acid, and ethchlorvynol, have been shown to produce pleural effusions. In the oleic acid and ethchlorvynol models, the development of pleural
effusions lagged behind interstitial and alveolar edema by several hours. In the oleic acid model, 35% of the excess lung water is collected in the pleural spaces. It appears that the pleura act as a reservoir for excess lung water in increased permeability and hydrostatic pulmonary edema. These effusions tend to be underdiagnosed clinically because the patient has bilateral alveolar infiltrates, and the radiograph is taken with the patient in a supine position. Experimentally, the effusion is serous to serosanguineous, with a predominance of PMNs. These effusions usually require no specific therapy and resolve as ARDS resolves. However, in a series of positive end-expiratory pressure (PEEP) unresponsive patients with ARDS, drainage of pleural effusion via tube thoracostomy has been shown to result in improved oxygenation [57]. The decision to proceed to pleural space drainage in ARDS should be approached on a case-by-case basis and is not generally recommended.

**Spontaneous Esophageal Rupture**

Esophageal rupture, a potentially life-threatening event, requires immediate diagnosis and therapy. The history in spontaneous esophageal rupture is usually severe retching or vomiting or a conscious effort to resist vomiting. In some patients, the perforation may be silent. Early recognition of spontaneous rupture depends on interpretation of the chest radiograph. Several factors influence chest radiograph findings: the time between perforation and chest radiograph examination, site of perforation, and mediastinal pleural integrity. A chest radiograph taken within minutes of the acute injury is usually unremarkable. Mediastinal emphysema probably requires at least 1 to 2 hours to be demonstrated radiographically and is present in less than half of patients; mediastinal widening may take several hours. Pneumothorax, present in 75% of patients with spontaneous rupture, indicates violation of the mediastinal pleura; 70% of pneumothoraces are on the left, 20% are on the right, and 10% are bilateral [65]. Mediastinal air is seen early if pleural integrity is maintained, whereas pleural effusion secondary to mediastinitis tends to occur later. Pleural fluid, with or without associated pneumothorax, occurs in 75% of patients. A presumptive diagnosis should immediately be confirmed radiographically. Esophagrams are positive in approximately 90% of patients [65]. In the upright patient, rapid passage of the contrast material may not demonstrate a small rent; therefore, the study should be done with the patient in the appropriate lateral decubitus position [66].

Pleural fluid findings depend on the degree of perforation and the timing of thoracentesis from injury. Early thoracentesis without mediastinal perforation shows a sterile, serous exudate with a predominance of PMNs, a pleural fluid amylase less than serum, and pH
greater than 7.30 [67]. Once the mediastinal pleura tears, amylase of salivary origin appears in the fluid in high concentration [68]. Because the pleural space is seeded with anaerobic organisms from the mouth, the pH falls rapidly and progressively to approach 6.00 [67]. Other pleural fluid findings suggestive of esophageal rupture include the presence of squamous epithelial cells and food particles. The diagnosis of spontaneous esophageal rupture dictates immediate operative intervention. If diagnosed and treated appropriately within the first 24 hours with primary closure and drainage, survival is greater than 90%. Delay from the time of initial symptoms to diagnosis results in a reduced survival with any form of therapy.

Hemothorax

Hemothorax (blood in the pleural space) should be differentiated from a hemorrhagic pleural effusion, because the latter can be the result of only a few drops of blood in pleural fluid. An arbitrary, but practical, definition of a hemothorax with regard to therapy is a pleural fluid to blood hematocrit ratio greater than 30%. The majority of hemothoraces results from penetrating or blunt chest trauma. Hemothorax can also result from invasive procedures, such as placement of central venous catheters, thoracentesis, and pleural biopsy, and pulmonary infarction, malignancy, or ruptured aortic aneurysm. Bleeding can occur from vessels of the chest wall, lung, diaphragm, or mediastinum. Blood that enters the pleural space clots, rapidly undergoes fibrinolysis, and becomes defibrinogenated; thus, it rarely causes significant pleural fibrosis.

Hemothorax should be suspected for any patient with blunt or penetrating chest trauma. If a pleural effusion is found on the admitting chest radiograph, thoracentesis should be performed immediately and the hematocrit measured on the fluid. The hemothorax may not be apparent on the initial chest radiograph, which may be because of the supine position of the patient. Because bleeding may be slow and not appear for several hours, it is imperative that serial radiographs be obtained for these patients. The incidence of concomitant pneumothorax is high (approximately 60%). Patients with traumatic hemothorax should be treated with immediate tube thoracostomy [69]. Large diameter chest tube drainage evacuates the pleural space, may tamponade the bleeding (especially if the origin is from a pleural laceration), allows monitoring of the bleeding, and decreases the likelihood of subsequent fibrothorax [69]. If bleeding continues without signs of slowing, thoracotomy should be
performed, depending on the individual circumstance [69]. Pleural effusions occasionally occur after removal of the chest tube from traumatic hemothoraces [70]. A diagnostic thoracentesis is indicated to exclude empyema. If empyema is excluded, the pleural effusion usually resolves without specific treatment and without residual pleural fibrosis. Hemothorax is a rare complication of anticoagulation that has been reported among patients receiving heparin and warfarin. Coagulation studies are usually within the therapeutic range. The hemothorax tends to occur on the side of the pulmonary embolism. Anticoagulation should be discontinued immediately, a chest tube inserted to evacuate the blood, and a vena cava filter considered.

Coronary Artery Bypass Surgery

A small, left pleural effusion is virtually always present after coronary artery bypass surgery. This is associated with left lower lobe atelectasis and elevation of the left hemidiaphragm on chest radiograph. Left diaphragm dysfunction is secondary to intraoperative phrenic nerve injury from cold cardioplegia, stretch injury, or surgical trauma [71,72]. The larger and grossly bloody effusions tend to be associated with internal mammary artery grafting, which causes marked exudation from the bed where the internal mammary artery was harvested [73]. The pleural fluid is a hemorrhagic exudate with a low nucleated cell count, a glucose level similar to that of serum, and a pH greater than 7.40. Rarely, a loculated hemothorax may develop with trapped lung, resulting in clinically significant restriction [74]. If there is a large effusion that qualifies as a hemothorax (see previous section), the fluid should be drained by tube thoracostomy. It is also prudent to drain moderately large, bloody effusions to avoid later necessity for decortication.

Abdominal Surgery

Approximately half of the patients who undergo abdominal surgery develop small unilateral or bilateral pleural effusions within 48 to 72 hours of surgery [27]. The incidence is higher after upper abdominal surgery, in patients with postoperative atelectasis, and in patients who have free ascitic fluid at the time of surgery. Larger left-sided pleural effusions are common after splenectomy [27]. The effusion is usually an exudate with less than 10,000 nucleated cells per μL. The glucose level is similar to that of serum, and pH is usually greater than 7.40. The effusion usually is related to diaphragmatic irritation or atelectasis. Small effusions generally do not require diagnostic thoracentesis, are of no clinical significance, and resolve spontaneously. Pleural effusion from subphrenic abscess or pulmonary embolism is unlikely to occur within 2
to 3 days of surgery. The only indication for diagnostic thoracentesis would be to exclude infection if the effusion is relatively large or loculated.

**Chylothorax**

Trauma from surgery accounts for approximately 25% of cases of chylothorax, second only to lymphoma. Most series estimate an incidence of chylothorax of less than 1% after thoracic surgery [75], but a 3% incidence has been reported after esophagectomy [76,77]. Virtually all intrathoracic procedures, including lobectomy, pneumonectomy, and coronary artery bypass grafting, have been reported to cause chylothorax. Other iatrogenic chylothoraces can be caused by complications of prolonged central vein catheterization. Nonsurgical trauma, such as penetrating and nonpenetrating neck, thoracic, and upper abdominal injuries, has also been associated with chylothorax.

When the thoracic duct is torn by stretching during surgery, chyle leaks into the mediastinum and subsequently ruptures through the mediastinal pleura. In the nonsurgical setting, penetrating injuries and fractures may directly tear the thoracic duct. Chylothorax from a central venous catheter usually involves venous thrombosis. Other rare causes of chylothorax include sclerotherapy of esophageal varices and translumbar aortography [78,79].

The patient may be asymptomatic if the effusion is small and unilateral, or may present with dyspnea with a large unilateral effusion or bilateral effusions. The pleural fluid is usually milky, but 12% can be serous or serosanguineous [80], with less than 7,000 nucleated cells per μL, virtually all lymphocytes. The pleural fluid pH is alkaline (7.40 to 7.80), and triglyceride levels are greater than plasma levels. Finding a pleural fluid triglyceride concentration of greater than 110 mg per dL makes the diagnosis of chylothorax highly likely. If the triglyceride level is less than 50 mg per dL, chylothorax is highly unlikely. Triglyceride levels of 50 to 110 mg per dL indicate the need for lipoprotein electrophoresis [80]; the presence of chylomicrons confirms a chylothorax. The thoracic duct defect after trauma usually closes spontaneously within 10 to 14 days, with chest tube drainage as well as bed rest and total parenteral nutrition to minimize chyle formation. A pleuroperitoneal shunt relieves dyspnea, recirculates chyle, and prevents malnutrition and immunocompromise.

**Duropleural Fistula**

Disruption of the dura and parietal pleura by surgical and nonsurgical trauma may result in a duropleural fistula with subsequent development of a pleural effusion [81–84]. The pleural fluid characteristics depend on
the severity of the trauma and the delay between the trauma and the pleural fluid analysis. Pleural fluid because of a chronic duropleural fistula is usually a colorless transudate with low mononuclear cell count; a duropleural fistula associated with recent trauma may be a transudate or an exudate [83,84]. The diagnosis may even be delayed because of a coexisting process such as hemothorax. The diagnosis of duropleural fistula is established by the detection of β₂-transferrin in the pleural fluid [85]. Confirmation of the fistula by conventional or radionuclide myelography is recommended if surgical management is contemplated.
PNEUMOTHORAX

Definition and Classification

Pneumothorax refers to air in the pleural space. Free air may also be found in the adventitial planes of the lung or the mediastinum (pneumomediastinum).

Spontaneous pneumothorax occurs without an obvious cause as a consequence of the natural course of a disease process. Primary spontaneous pneumothorax occurs without clinical findings of lung disease. Secondary spontaneous pneumothorax occurs as a consequence of clinically manifest lung disease, the most common being COPD. Traumatic pneumothorax results from penetrating or blunt chest injury. Iatrogenic pneumothorax occurs as an inadvertent consequence of diagnostic or therapeutic procedures.

Pathophysiology

Pressure in the pleural space is subatmospheric throughout the normal respiratory cycle, averaging approximately −9 mm Hg during inspiration and −5 mm Hg during expiration. Because of airways resistance, pressure in the airways is positive during expiration (+3 mm Hg) and negative (−2 mm Hg) during inspiration. Thus, in normal breathing, airway pressure is greater than pleural pressure throughout the respiratory cycle. Airway pressure may be increased markedly with coughing or strenuous exercise; however, pleural pressure rises concomitantly so that the transpulmonary pressure gradient is usually not substantially changed. When there are rapid fluctuations in intrathoracic pressure, however, a large transpulmonary pressure gradient occurs transiently. Bronchial and bronchiolar obstruction, resulting in air trapping, can significantly increase the transpulmonary pressure gradient. The alveolar walls and visceral pleura maintain the pressure gradient between the airways and pleural space. When the pressure gradient is transiently increased, alveolar rupture may occur; air enters the interstitial tissues of the lung and may enter the pleural space, resulting in a pneumothorax. If the visceral pleura remains intact, the interstitial air moves toward the hilum, resulting in pneumomediastinum. Because mean pressure within the mediastinum is always less than in the periphery of the lung, air moves proximally along the bronchovascular sheaths to the hilum and
mediastinal soft tissues. The development of pneumomediastinum after alveolar rupture requires continual cyclic respiratory efforts, which result in slow movement of air from the ruptured alveolus along a pressure gradient to the mediastinum. Mediastinal air may decompress into the cervical and subcutaneous tissues or the retroperitoneum. With abrupt rise in mediastinal pressure or insufficient decompression to subcutaneous tissue, the mediastinal pleura may rupture, causing pneumothorax. Inadequate decompression of the mediastinum, rather than direct rupture of subpleural blebs into the pleural space, may be the major cause of pneumothorax.

When pneumothorax occurs, the elasticity of the lung causes it to collapse. Lung collapse continues until the pleural defect seals or pleural and alveolar pressures equalize. When a ball valve effect occurs at the site of communication between the pleural space and the alveolus, permitting only egress of air from the lung, there is a progressive accumulation of air within the pleural space, which can result in markedly increased positive pleural pressure, resulting in tension pneumothorax. Tension pneumothorax compresses mediastinal structures, resulting in impaired venous return to the heart, decreased cardiac output, and, at times, fatal cardiovascular collapse [86,87]. Rarely, tension along the bronchovascular sheaths and in the mediastinum can cause collapse of the pulmonary arteries and veins, resulting in cardiovascular collapse.

Patients with primary spontaneous pneumothorax have a decrease in vital capacity and an increase in the \(P(A−a)O_2\) gradient, and usually present with hypoxemia owing to predominantly development of an intrapulmonary shunt and areas of low ventilation–perfusion in the atelectatic lung [88]. Hypercapnia does not occur because there is adequate function in the uninvolved lung to maintain necessary alveolar ventilation. Patients with secondary spontaneous pneumothorax, in contrast, commonly develop hypercapnia because the gas exchange abnormality caused by the pneumothorax is superimposed on lungs with preexisting abnormal pulmonary gas exchange.

**Pneumothorax of the Critically Ill**

Patients with secondary spontaneous pneumothorax may be admitted to an ICU because they develop severe hypoxemic and, at times, hypercapnic respiratory failure. Patients with primary spontaneous pneumothorax rarely require ICU admission because the contralateral lung can maintain necessary alveolar ventilation, and the hypoxemia can be managed with supplemental oxygen. The most common causes of pneumothoraces among ICU patients are invasive procedures and barotrauma.
Iatrogenic Pneumothorax

Central Venous Catheters. Central venous catheters are used routinely for critically ill patients for volume resuscitation, parenteral nutrition, and drug administration. Approximately 3 million central venous catheters are placed annually in the United States, and this procedure continues to be associated with clinically relevant morbidity and some mortality. The morbidity and mortality associated with central venous catheter use are most commonly physician related. Pleural complications of acquisition of venous access and the indwelling phase of central venous catheters include pneumothorax, hydrothorax, hemothorax, and chylothorax. In a recent study of mechanical complications of central venous catheters, 1.1% of 534 patients had pneumothorax [89]. This translates into approximately 33,000 pneumothoraces per year from central venous catheter insertions in critically ill patients in the United States. In the same study, none of the 405 patients developed pneumothorax when the central venous catheter was replaced over a guidewire.

The subclavian and internal jugular routes have been associated with pneumothorax, hemothorax, chylothorax, and catheter placement into the pleural space. Cannulation of the subclavian vein is associated with a higher risk of pneumothorax (less than 5%) [90] than cannulation of the internal jugular vein (less than 0.2%) [91]; with the external jugular venous approach, pneumothorax is avoided. There is a greater risk of pneumothorax with the infraclavicular compared to the supraclavicular approach to the subclavian vein. All complications of insertion, regardless of approach, can be reduced by appropriate physician training and experience. Operator inexperience appears to increase the number of complications with the internal jugular approach. It probably does not have as much impact on the incidence of pneumothorax with the subclavian vein approach, which accounts for 25% to 50% of all complications [92].

Most pneumothoraces occur at the time of the procedure from direct lung puncture, but delayed pneumothoraces have been noted; therefore, it is prudent to perform an ultrasonographic examination or view a chest radiograph 12 to 24 hours after the procedure. Up to half of the patients with needle puncture pneumothorax may be managed expectantly without the need for tube drainage. Bilateral pneumothoraces have been reported to occur from unilateral attempts [92], and death can occur when there is a delay in the diagnosis of pneumothorax. As stated previously, a pneumothorax may be more difficult to detect while the patient is supine. Additional views should be taken, especially if the venous cannulation does not proceed as anticipated. With any newly placed central venous catheter, a postprocedure chest radiograph should
be obtained, regardless of the site cannulated, to assure that the catheter tip is properly positioned. If a small pneumothorax is diagnosed by chest radiograph and the patient is asymptomatic and not on mechanical ventilation, the patient can be followed expectantly with repeat chest radiographs to assure that the leak has ceased. If the patient is on mechanical ventilation or the pneumothorax is large or has caused significant symptoms or gas exchange abnormalities, then tube thoracostomy should be performed as soon as possible.

**Barotrauma.** Pulmonary barotrauma is an important clinical problem because of the widespread use of mechanical ventilation. Barotrauma occurs in approximately 3% to 10% of mechanically ventilated patients and includes parenchymal interstitial gas, pneumomediastinum, subcutaneous emphysema, pneumoperitoneum, and pneumothorax [75,93–95]. The most clinically important form is pneumothorax, occurring in 1% to 15% of all mechanically ventilated patients. For patients with ARDS, rates of 6.5% to 87% have been reported [94,95]. The number of ventilator days, underlying disease (ARDS, COPD, or necrotizing pneumonia), and use of PEEP have an impact on the incidence of pneumothorax. When a pneumothorax develops during mechanical ventilation, 30% to 97% of patients develop tension. The reported incidence of barotrauma varies widely between the studies with the lowest incidences reported among the most large series [95]. This may be partly explained by the adoption of less aggressive ventilation strategies over time.

The initial radiographic sign of barotrauma is often pulmonary interstitial gas or emphysema [96]. In the early stages, however, interstitial gas may be difficult to detect radiographically. This harbinger of pneumothorax may be detected as distinct subpleural air cysts, linear air streaks emanating from the hilum, and perivascular air halos. Subpleural air cysts, most commonly seen among patients with ARDS, tend to appear abruptly on the chest radiograph as single or multiple thin-walled, round lucencies, and are most often visualized at the lung bases, medially or diaphragmatically [97]. The cysts, which may expand rapidly, are usually 3 to 5 cm in diameter. Differentiating between peripheral subpleural air cysts and a localized basilar pneumothorax may be problematic. Pleural air cysts appear to be more common among younger patients, possibly because connective tissue planes of the lung are looser in younger patients than in older patients. The risk of tension pneumothorax is substantial among patients who have developed
subpleural lung cysts with continued mechanical ventilation. When mechanical ventilation is discontinued, the cyst may resolve spontaneously or become secondarily infected.

Ultrasound has emerged as a bedside modality for the detection of pneumothorax. The absence of lung sliding is the finding associated with pneumothorax [5]. False-positive results may occur and are because of bullous lung disease or preexisting pleural symphysis [5,98,99]. The disappearance of lung sliding that was present previously may be more specific for the development of pneumothorax; for example, after line placement. However, this subject awaits further study.

When evidence of barotrauma without pneumothorax is observed in any patient requiring continued mechanical ventilation, immediate attempts should be made to lower the plateau airway pressure. Among those with ARDS, tidal volumes [100] and inspiratory flow rates should be lowered, an attempt should be made to reduce or remove PEEP, and neuromuscular blockers and sedation should be considered [101]. Among those with status asthmaticus, in addition to the aforementioned maneuvers, controlled hypoventilation should be accomplished [102,103]. There is no evidence supporting the use of prophylactic chest tubes. However, the patient should be monitored closely for tension pneumothorax and provisions made for emergency bedside tube thoracostomy.

**Tension Pneumothorax**

Pneumothorax among the mechanically ventilated patient usually presents as an acute cardiopulmonary emergency, beginning with respiratory distress and, if unrecognized and untreated, progressing to cardiovascular collapse. In one report of 74 patients, the diagnosis of pneumothorax was made clinically for 45 patients (61%) based on hypotension, hyperresonance, diminished breath sounds, and tachycardia. The mortality rate was 7% among these patients diagnosed clinically. In the remaining 29 patients, diagnosis was delayed between 30 minutes and 8 hours, and 31% of these patients died of pneumothorax. Other series of barotrauma in the setting of mechanical ventilation have reported mortality rates from 58% to 77% [75].

Tension pneumothorax can be lethal when diagnosis and treatment are delayed. The diagnosis should be made clinically at the bedside for the patient on mechanical ventilation who develops a sudden deterioration characterized by apprehension, tachypnea, cyanosis, decreased ipsilateral breath sounds, subcutaneous emphysema, tachycardia, and hypotension. The diagnosis may be problematic among the unconscious, the elderly, and the patient with bilateral tension, which may be more protective of the mediastinal structures and lessen the impact on cardiac output.
For the unconscious or critically ill patient, hypoxemia may be one of the earlier signs of tension pneumothorax. For the patient on mechanical ventilation, increasing peak and plateau airway pressure, decreasing compliance, and auto-PEEP should raise the possibility of tension pneumothorax. Difficulty with bag valve mask ventilation, the patient with greater than expected force required to deliver adequate tidal volumes should prompt consideration of tension pneumothorax.

When the clinical signs and symptoms are noted among mechanically ventilated patients, treatment should not be delayed to obtain radiographic confirmation. If a chest tube is not immediately available, placement of a large-bore needle into the anterior second intercostal space on the suspected side is life-saving and confirms the diagnosis, because a rush of air is noted on entering the pleural space. An appropriately large chest tube can then be placed and connected to an adequate drainage system that can accommodate the large air leak that may develop among mechanically ventilated patients [103].

On relief of the tension, there is a rapid improvement in oxygenation, increase of blood pressure, decrease of heart rate, and fall in airway pressures. In experimental tension pneumothorax, it has been observed that the inability to raise cardiac output in response to hypoxemia leads to a reduction in systemic oxygen transport and a decrease in mixed venous partial pressure of oxygen (PO$_2$), partially explaining the cardiovascular collapse seen in these patients [87]. For mechanically ventilated patients, a decrease in cardiac output is an inevitable consequence of tension pneumothorax.
BRONCHOPLEURAL FISTULA

Definition and Causes

Communication between the bronchial tree and the pleural space is a dreaded complication of mechanical ventilation. There are three presentations of bronchopleural fistula (BPF): (a) failure to reinflate the lung despite chest tube drainage or continued air leak after evacuation of the pneumothorax in the setting of chest trauma; (b) complication of a diagnostic or therapeutic procedure, such as thoracic surgery; and (c) complication of mechanical ventilation, usually for those with ARDS [86]. Among those with ARDS, a pneumothorax often occurs under tension and is later associated with empyema, multiple sites of leakage, and a poor prognosis. A large air leak through a BPF can result in failure of lung reexpansion, loss of a significant amount of each delivered tidal volume, loss of the ability to apply PEEP, inappropriate cycling of the ventilator, and inability to maintain alveolar ventilation (Table 176.3).

If there is a continued air leak for longer than 24 hours after the development of pneumothorax, then a BPF exists. The main factors that perpetuate BPF are high airway pressures that increase the leak during inspiration, increased mean intrathoracic pressures throughout the respiratory cycle (PEEP, inflation hold, high inspiratory to expiratory ratio) that increase the leak throughout the breath, and high negative suction. Among those with severe ARDS, all of these factors are present because they usually are necessary to support gas exchange.

Management
Given the frequency of barotrauma in BPF among mechanically ventilated patients, intensivists are called to give advice on the management of these difficult patients. Definitive therapy of BPF frequently involves invasive surgical approaches that include thoracoplasty, mobilization of the pectoralis or intercostal muscles, bronchial stump stapling, and decortication [104,105]. Although some of these techniques are still used today, there is a trend toward more conservative management of acute and chronic BPF, using innovations of standard techniques and new modalities that include chest tube management, drainage systems, ventilatory support, and definitive nonoperative therapy (Table 176.4). Insertion of an endobronchial valve designed for the treatment of emphysema may be considered in selected patients [106]. Nonoperative therapy provides an alternative to the surgical approaches in patients who are poor operative candidates. Each patient with a BPF is unique and requires individual management based on the specific clinical setting. Attention to the basics of medical care of patients with BPF should not be neglected in the face of the potentially dramatic events related to the BPF. Nutritional status must be maintained, appropriate antibiotics used for the infected pleural space, and the space adequately drained.

Chest Tubes

The initial therapy for pneumothorax for a patient on mechanical ventilation is placement of a chest tube in an attempt to reexpand the lung (see Chapter 13). The chest tube is initially necessary, can be detrimental later, and may play a role more important than that of a passive conduit. Air leaks in the setting of BPF range from less than 1 to 16 L per minute [107]; therefore, a chest tube that permits prompt and efficient drainage of this level of airflow is required. The smallest internal diameter that allows a maximum flow of 15.1 L per minute at −10 cm H₂O suction is 6 mm (a 32-Fr chest tube has an internal diameter of 9 mm). A chest tube with a diameter adequate to convey the potentially large airflow of the BPF must be considered. A chest tube with too small diameter can lead to lung collapse and tension pneumothorax in the setting of a mobile mediastinum.

Not only can the chest tube be used to drain pleural air, it can also be used to limit the air leak in certain situations. One modality is the application of intrapleural pressure equivalent to the level of PEEP during the expiratory phase of ventilation [108,109]. With positive intrapleural pressure applied through the chest tube, the air leak persists during the inspiratory phase of ventilation but decreases during expiration, allowing maintenance of PEEP in patients in whom it is necessary for adequate oxygenation. Synchronized closure of the chest tube during the inspiratory phase has also been used to limit air leak [110,111]. A combination of these techniques has been suggested for patients with significant BPF air leaks during both the inspiratory and expiratory phases of mechanical ventilation [111,112]. These techniques pose potential hazards, including increased pneumothorax and tension pneumothorax [110,112], necessitating extremely close patient monitoring when such manipulations are used.

Instillation of chemical agents through the chest tube may potentially help close the BPF if the anatomic defect is small and single, but it is unlikely to be successful if the fistula is large or if there are multiple fistulas. Various agents have been successful in preventing recurrent pneumothoraces in patients who are not on mechanical ventilation [113–115], but BPF in the setting of mechanical ventilation is a different situation. One study compared the recurrence of pneumothorax in 39 patients with BPF randomized to intrapleural tetracycline or placebo groups [116]. There was no evidence that intrapleural tetracycline facilitated closure of the BPF. No adverse effects were encountered from the instillation of tetracycline in patients with persistent air leaks.

The chest tube may be associated with adverse effects among patients with BPF. The gas escaping through the chest tube represents part of the minute ventilation delivered to the patient and makes maintenance of an
effective tidal volume problematic. Maintenance of a specific level of ventilation is not only affected by the amount of gas escaping through the fistula. The escaping gas does not passively flow from the airways into the BPF but is involved in physiologic gas exchange [117,118]. Approximately 25% of the minute ventilation has been found to escape via the BPF among patients with ARDS, with more than 20% of CO$_2$ excretion occurring by this route for half of the patients [118]. The role of the BPF in active CO$_2$ exchange is complex: Proposed mechanisms include drainage of gas from alveoli in the area of the BPF and removal of gas from remote alveolar areas by pressure gradients created by the BPF [119].

Carbon dioxide excretion and a reduction of minute ventilation occur to a lesser extent in BPF trauma victims [117]. In these patients, variable CO$_2$ excretion and loss of minute ventilation were dynamic and depend on the level of chest tube suction. The difference between trauma and ARDS patients may have been because of the variability of lung compliance and the use of different ventilators [118]. Also, BPF may affect oxygen use, which generally decreases the use of inspired oxygen before it escapes through the fistula [117]. This relationship is variable but requires consideration for patients with impaired oxygenation.

Negative pressure applied to the chest tube may be transmitted beyond the pleural space and into the airways, creating inappropriate cycling of the ventilator [119]. The increased flow through a BPF can occur with increased negative pleural pressure and may interfere with closure and healing of the fistulous site [112]. Therefore, the least amount of chest tube suction that keeps the lung inflated should be maintained in patients with BPF. The chest tube is a potential source of infection, both at the insertion site and within the pleural space.

**Drainage Systems**

As with the chest tube, the resistance of flow of gases is a consideration for the choice of the drainage system for the patient with a BPF [107]. The size of the air leak and the flow that the drainage system can accommodate are necessary considerations. In an experimental model of BPF that simulated the type of air leak seen clinically (mean maximal flow, 5 L per minute), four pleural drainage units (PDUs) (Emerson Post-Operative Pump, Emerson; Pleur-Evac, Teleflex Medical; Sentinel Seal, Tyco; and Thora-Klex, Avilor) were tested at water seal, −20 cm H$_2$O, and
−40 cm H₂O suction [107]. Compared with the water seal, −20 cm H₂O suction significantly increased the ability of all four PDUs to evacuate air via the chest tube, but an increase in suction to −40 cm H₂O did not significantly alter flow. When the air leak reached 4 to 5 L per minute, use of the Thora-Klex or Sentinel Seal became clinically impractical. The Pleur-Evac can handle flow rates up to 34 L per minute, but its use with rates greater than 28 L per minute is impractical owing to intense bubbling in the suction control chamber. Air leaks of this magnitude are infrequent clinically in BPF and are likely to be seen only with major airway disruption or diffuse parenchymal leak secondary to ARDS with severe barotraumas [119]. In the latter situations, the low-pressure, high-volume Emerson suction pump remains the only PDU capable of handling the air leak [107]. The choice of PDU should be influenced by its physiologic capabilities and the type of BPF air leak that is encountered.

Mechanical Ventilation

**Conventional Ventilation.** The dilemma with a BPF in a mechanically ventilated patient is achieving adequate ventilation and oxygenation while allowing repair of the BPF to occur. Because air flow escaping through a BPF theoretically delays healing of the fistulous site, reducing flow through the fistula has been a major goal in promoting repair. The BPF provides an area of low resistance to flow and acts as a conduit for the escape of a variable percentage of delivered tidal volume during conventional positive-pressure mechanical ventilation. Thus, the goal of management is to maintain adequate ventilation and oxygenation while reducing the fistula flow [112]. Using the lowest possible tidal volume, fewest mechanical breaths per minute, lowest level of PEEP, and shortest inspiratory time (see Chapter 166) can do this. Avoidance of expiratory retard also reduces airway pressures. Using the greatest number of spontaneous breaths per minute, thereby reducing use of positive pressure, may also be advantageous. Intermittent mandatory ventilation or pressure modes of ventilation may have advantages over assist-control ventilation for managing the air leak of BPF.

In a retrospective study of 39 patients with BPF who were maintained on conventional ventilation, only two patients developed a pH less than 7.30 despite air leaks of up to 900 mL per breath [119]. Overall, mortality was higher when the BPF developed late in the illness and was higher with larger leaks (more than 500 mL per breath).

**High-Frequency Ventilation.** Despite anecdotal reports, experimental data, and clinical studies involving high-frequency ventilation (HFV) in the setting of BPF, controversy exists. However, there appear to be subgroups of patients with BPF in whom HFV may be
beneficial. Both animal [120] and human [121] studies suggest that HFV is superior to conventional ventilation in controlling \( \text{PO}_2 \) and partial pressure of carbon dioxide \( (\text{PCO}_2) \) when there is a proximal (tracheal or bronchial) unilateral or bilateral fistula in the presence of normal lung parenchyma.

The use of HFV in BPF in patients with parenchymal lung disease, such as ARDS, is more controversial. Although some studies have shown that HFV improves or stabilizes gas exchange for patients with extensive parenchymal lung disease, others have not shown a beneficial effect on gas exchange or a reduction in fistula outflow [122,123]. A trial of HFV appears reasonable for the patient with a proximal BPF and normal lung parenchyma; however, it is unclear whether HFV should be considered the primary mode of ventilation in this setting. Despite discrepancies of clinical results, a trial of HFV for selected critically ill patients with a BPF and diffuse parenchymal disease who appear to be failing conventional ventilation may be justified. Caution must be exercised, however, with close monitoring of gas exchange parameters and fistula flow whenever HFV is used.

**Other Modes of Ventilation.** Other maneuvers during both conventional ventilation and HFV can be potentially helpful in patients with BPF. Selective intubation and conventional ventilation of the unaffected lung in patients with unilateral BPF may be useful but predisposes to the collapse of the nonintubated lung [124,125]. The use of differential lung ventilation with conventional ventilation may be of benefit for some patients [122]. Positioning of the patient such that the BPF is dependent has been shown to decrease fistula flow [125].

Case reports and animal studies suggest other potential applications of HFV for BPF, including the use of independent lung ventilation with HFV applied to the BPF lung and conventional ventilation to the normal lung [126]. Another mode of HFV, ultra–high-frequency jet ventilation, is being explored and has been used with some success for reducing BPF in humans [127] and animal models [128]. Independent lung ventilation with ultra–high-frequency lung ventilation applied to the BPF lung and conventional ventilation to the normal lung led to rapid BPF closure in two of three patients [127].

**Flexible Bronchoscopy**

The flexible bronchoscope can be valuable in the diagnosis of BPF. Bronchoscopic therapy of BPF has several potential advantages, including low cost, shortened hospital stay, and relative noninvasiveness, particularly in poor operative candidates [129–133] (see Chapter 10). Proximal fistulas, such as those associated with lobectomy or pneumonectomy or stump breakdown, can be directly visualized through
the bronchoscope. Distal fistulas cannot be visualized directly and require bronchoscopic passage of an occluding balloon to localize the bronchial segment leading to the fistula [132,133]. A balloon is systematically passed through the working channel of the bronchoscope and into each bronchial segment in question and then inflated; a reduction in air leak indicates localization of a bronchial segment communicating with the BPF. Once the fistula has been localized, various materials can be passed through a catheter in the working channel of the bronchoscope and into the area of the fistula [129–137]. Direct application of a sealant through the working-channel catheter onto the fistula site is the method generally used for directly visualized proximal fistulas. For distal fistulas, a multiple-lumen Swan–Ganz’s catheter has been used to localize the BPF and pass the occluding material of choice [132].

Several agents have been used through the bronchoscope in an attempt to occlude BPF. These include fibrin agents cyanoacrylate-based agents, absorbable gelatin sponge (Gelfoam, Pfizer), blood tetracycline, and lead shot [131–133]. The reports on all of these agents are limited to only a few patients. The cyanoacrylate-based and fibrin agents have received the most attention but still have had less than 20 total cases reported. These patients have had at least a 50% reduction of fistula flow, and most had closure of the fistula subsequent to sealant application, although multiple applications were necessary in some patients. These agents appear to work in two phases, with the agent initially sealing the leak by acting as a plug and subsequently inducing an inflammatory process with fibrosis and mucosal proliferation permanently sealing the area [129]. They are not useful with large proximal tracheal or bronchial ruptures or multiple distal parenchymal defects [132].

Gas Embolism Syndromes

MARK M. WILSON

The gas embolism syndromes occur in many different settings and may result in life-threatening emergencies. The clinical manifestations of these disorders are varied, and the final pathophysiologic consequences depend on where the gas bubbles obstruct the circulation and how they impact the function of the surrounding tissue. The nervous system, heart, lungs, and skin are the organ systems most frequently involved. The diagnosis of a gas embolism syndrome can be very difficult to establish. Clinicians must depend on a high level of suspicion in the appropriate settings to rapidly identify the problem, prevent further gas entry into the circulation, and begin effective treatment. Each of these entities is discussed in more detail based on the predominant location of the gas collections, although they are not always separate and distinct.

VENOUS GAS EMBOLISM

Although the actual incidence of venous gas embolism (VGE) in the United States is unknown, it has been estimated conservatively that at least 20,000 cases of “air” embolism occur annually [1]. The consequences of VGE range from clinically undetectable to being rapidly fatal.

Etiology

Clinical reports emphasize the high incidence of VGE in association with traumatic injuries and invasive procedures involving the head, neck, and chest (Table 177.1) [1]. Only the most common causes are discussed in detail in this chapter.

TABLE 177.1 Causes of Venous Gas Embolism
Surgical
- Any head/neck/cardiothoracic surgery
- Orthopedic surgery (arthroscopy, endoprosthesis placement)
- Hysterectomy, cesarean section
- Transurethral resection of the prostate
- Abortion, uterine curettage
- Normal childbirth, childbirth with placenta previa or extraction procedure
- Liver transplantation/resection

Traumatic
- Open/penetrating wounds
- Vena cava lacerations
- Positive-pressure mechanical ventilation
- Self-contained underwater breathing apparatus diving
- Decompression sickness
- Pneumothorax/pneumoperitoneum
- Cunnilingus/intercourse during pregnancy

Self-induced

Diagnostic and therapeutic procedures
- Central venous catheter insertion/removal
- Pulmonary artery catheterization
- Thoracoscopy, thoracentesis
- Pleurodesis, percutaneous lung biopsy
- Gravity infusion of blood/intravenous products
- Pressurized injections/infusions (including contrast media)
- Any involving gas insufflation
- Hemodialysis
- Pericardiocentesis
- Pacemaker/defibrillator placement
- Radiofrequency cardiac ablation
- Endoscopic retrograde cholangiopancreatography
- Epidural catheter insertion
- Neodymium:yttrium-aluminum-garnet laser therapy
- Liquid nitrogen cryosurgery
- Hydrogen peroxide irrigation/ingestion
- Blood donation
Surgical

Virtually, any surgical procedure that transiently exposes an open vein to a relative negative pressure may be associated with VGE. The best-studied surgical procedure known to be commonly associated with VGE is craniotomy performed in the Fowler’s (sitting) position. When monitors for VGE are prospectively used [1], VGE has been documented in 21% to 32% of all craniotomies and up to 58% of occipital craniotomies. Air may also enter the venous system via the occipital emissary veins, the dural sinuses, the diploic veins, the veins of tumors, or through burr holes.

Childbirth, hysterectomy, and abortion have been associated with an increased incidence of VGE [1]. It has been estimated that VGE causes 1% of maternal deaths. The incidence of VGE during cesarean section has been reported to be on the order of 39% to 71% overall, and the majority of episodes occur during uterine repair and placenta removal. During pregnancy, the veins of the uterus are exposed and fixed; when traumatized; they remain open and may serve as a portal of entry for gaseous emboli.

Prospective Doppler monitoring studies have documented a 31% to 83% incidence of VGE during total hip replacement [1]. The presumptive mechanism of embolization involves the forcible entry of air into the venous circulation through vascular openings of the bony medulla of the femur as a result of the high pressures generated in the distal shaft when the prosthesis is inserted.

Sinus lavage and dental surgical procedures have resulted in fatal cases of VGE [1]. Emboli are the result of intraosseous irrigation with water or air under pressure (at least 80 cm water). The cause of VGE during these procedures is not well understood.

Trauma

Open or penetrating wounds—especially of the chest, neck, head, heart, spine, abdomen, and pelvis—may result in VGE owing to the exposure of an open vein to a relative positive pressure gradient (i.e., atmospheric pressure as compared with central venous pressure) [1]. Pneumothorax or pneumoperitoneum may result in VGE by the inadvertent puncture of intrathoracic or intraabdominal blood vessels during the mechanism of injury.

Some of the more unusual cases of traumatic embolization include reports of self-induced VGE caused by urethral insufflation with an atomizer bulb, scrotal injection of air with a bicycle pump, and attempted in hospital suicide by forcible breathing into an intravenous line [1].
Diagnostic and Therapeutic Procedures

Air embolism in the setting of central venous catheterization has an unknown overall incidence, probably because the diagnosis is made only with large emboli. This fact also impacts the reported mortality rate in the literature of 29% to 50% [1]. Morbidity is also significant because 42% of all survivors of recognized VGE experienced residual neurologic deficits. Air can enter the central venous system in several different ways: (a) during needle/wire/catheter insertion; (b) with fracture of the catheter, malfunction of a self-sealing diaphragm, or detachment of external connections; (c) after removal of a catheter that has been in place for several days, such that air is “sucked” into an open subcutaneous tissue tunnel that has formed a skin tract; and (d) as a result of a piggyback infusion running dry [1].

Thoracoscopy may produce VGE presumably as a result of the associated pneumothorax. Lung biopsy by percutaneous or bronchoscopic techniques creates a direct traumatic opening at the blood–air interface. Significant embolization might result whenever a medium-sized vein is exposed [1].

Gas insufflation procedures have been associated with gaseous embolization [1]. Diagnostic procedures involving the female genital tract, urethra, urinary bladder, kidney, retroperitoneal and perirenal spaces, peritoneal and pleural cavities, joints, cerebral ventricles, epidural space, and paranasal sinuses all carry a risk for VGE. To minimize this risk, the volume of gas introduced, the pressure resulting within the cavity, and the rate of injection should always be as low as possible. It has been suggested that carbon dioxide (CO₂) should be used as the insufflating agent whenever possible because of its high blood solubility and rapid clearance. This last recommendation begs a word of caution, however, because VGE-associated deaths have been reported even with the use of CO₂ [1].

Placement of epidural catheters for anesthesia has been noted prospectively to be associated with Doppler-detectable VGE [1]. Among pregnant women placed in the left lateral decubitus position, VGE was noted to occur in 43%, almost half of whom were at least briefly symptomatic. The underlying mechanism relates to the rich plexus of veins of the epidural space, mostly anterior and lateral to the spinal cord. These veins are susceptible to trauma from a needle if the puncture is not directly in the midline or if the needle is rotated once in the epidural...
space. Because there are no valves in this plexus of veins, the intravascular pressure likely closely follows the central venous pressure. In the left lateral decubitus position, the site of puncture is above the level of the right atrium (RA), and, for pregnant women, uterine compression of the inferior vena cava is relieved, both of which serve to create a subatmospheric pressure in the epidural venous plexus.

Thermal tissue-ablation procedures using application of heat or cold have been associated with VGE [1]. Laser ablation/coagulation of tissues requires a continuous method for cooling of the laser tip. In general, these methods have involved using liquid (saline) or gas (air, nitrogen [N₂], CO₂). Reports exist in the literature of the entry of these compressed gases into the venous circulation owing to opening of vascular channels during the ablative procedure [1]. At the other temperature extreme, cryosurgery with instillation of liquid N₂ is used to extend the surgical margin of excision during cancer operations. Direct contact between the tissues and the liquid N₂ may lead to entry of N₂ into the circulation in the gaseous state [1]. N₂ gas expands because it is warmed to a volume of greater than 500 times that it occupied in the liquid state. Gas emboli of this magnitude could be rapidly fatal.

Ingestion or use of hydrogen peroxide (H₂O₂) in closed spaces or body cavities has been shown to result in fatal VGE [1]. Animal and human studies have shown that H₂O₂ is readily absorbed from the intestines and the peritoneum. Oxygen (O₂) emboli arise from the systemic absorption of H₂O₂ because catalase-induced decomposition causes release of water and molecular O₂. One milliliter of a 3% H₂O₂ solution releases an estimated 10 mL of O₂ in reaction with catalase [1], which is abundant in human blood.

Case reports of VGE during blood donation and insertion of peripheral intravenous catheters illustrate that whenever a vein is exposed to atmospheric pressure, there is a hazard of embolization [1].

Pathophysiology

Entry of Gas into the Circulation

VGE has been shown to occur among patients in essentially any position [1]. The critical factor common to all VGE lies in the pressure gradient produced between the right side of the heart and the level of the open vessel. Any increase in the distance of the open vessel above the level of the heart or any decrease in intrathoracic pressure would increase the likelihood of air entering the venous circulation and traveling to the
heart. For each 5 in. in vertical height above the level of the RA, there is an approximately 9.3 mm Hg decrease in local blood pressure. Any decrease of mean intrathoracic pressure or mechanisms resulting in a contracted blood volume or low central venous pressure will tend to enhance any existing venous pressure gradient. Large amounts of gas can rapidly pass into the venous system under the proper conditions. Calculations indicate that approximately 100 mL of air per second would enter a vessel via a No. 14G needle with only a 5 cm H$_2$O pressure gradient across it.

**Travel of Gas to the Heart**

Once the gas has entered the venous circulation, it travels toward the point of lower pressure until it becomes lodged at an area of obstruction or its passage is impeded or prevented by electrostatic forces between the interface of the bubble with the vascular endothelium overcoming the laminar flow in that vessel. Animal studies have found that passage of air emboli through the superior vena cava (SVC) can be retarded or the air even retained at sites proximal to the SVC for an indefinite period [1].

Large venous gas emboli are capable of lodging and then obstructing blood flow in the heart and the pulmonary vasculature [1]. Grossly, these events have been observed to cause immediate dilation of the RA, the right ventricle (RV), and the pulmonary outflow tract. A rapidly expanding zone of RV ischemia follows soon thereafter. Functional obstruction of the RV outflow tract may result owing to an “air lock” phenomenon. A blood–froth mixture results from systolic compression of the compressible gas phase with the noncompressible whole-blood phase. This concoction is then able to expand during diastole, the net result being an inadequate pumping action of the RV. It has been postulated that turbulent blood flow results from this “whipping” type of action or from vortex flow around partially obstructing collections of air bubbles. This whipping subsequently enhances fibrin formation, platelet aggregation, and coalescence of intravascular fat.

Smaller collections of air may not impair the heart, and they may pass directly to the pulmonary arteries. Larger collections enter the pulmonary arteries with associated collections of fat and fibrin emboli.

**Fate of Gas Emboli**

Bubbles with the smallest initial radii have the shortest life span and are occasionally seen to pass directly through a capillary bed after attaining a radius of approximately 5 $\mu$m [1]. The bulk of excretion of gaseous emboli is accounted for by molecular diffusion across the capillary wall into the alveolar spaces. The rate of washout is related to RV performance and
mean pulmonary artery (PA) pressure [1].

Surface–tension relationships, vascular pressures, and the size range of the bubbles are additional factors that influence passage of emboli across the lungs. In addition, the composition of the gas influences the size of the bubbles and the rate of dissolution in the blood. Bubbles of air or N₂ would be expected to remain in the blood for longer periods of time than O₂ or CO₂, especially if the ventilatory gases resemble room air composition. This relationship is because of the similarity of the partial pressures of the gases inside the bubbles with those of the surrounding blood, as well as to the different solubilities of the gases. Tonic factors affecting the diameter of pulmonary vessels (e.g., anesthetic agents, neurogenic or hypoxic pulmonary vasoconstriction, arterial tension of CO₂, endogenous mediators) also influence the passage of bubbles across the lungs.

Cardiopulmonary Consequences of Embolization

Pulmonary vascular obstruction is a major consequence of VGE and can lead to death. Obstruction to blood flow through the RV and through the pulmonary vascular system results from pulmonary vasoconstriction and from the mechanical impediment to flow imposed by the gas bubbles [1]. The change in PA pressures depends on whether the gas emboli are the result of a slow continuous infusion or a rapid bolus injection. In the first instance, a brisk increase in PA pressure to a level of up to 300% of baseline is seen [1]. This rapid increase phase is believed to be as a result of pulmonary vascular vasoconstriction and is followed by a plateau phase. The plateau response likely represents the opening of anatomic intrapulmonary shunts or a balance between the rate of gas infusion and rate of elimination. In contrast, when approximately 100 mL of air is injected as a bolus, PA pressure declines by as much as 20%, because the right heart is acutely stressed beyond its capabilities. Larger bolus injections (125 to 200 mL) are consistently fatal.

Pulmonary edema from VGE has been described anecdotally among humans [1]. Increased hydrostatic pulmonary vascular pressures (from mechanical occlusion of the PA and from induced vasoconstriction) and increased capillary permeability have been suggested as mechanisms for edema formation [1]. Regardless, the edema proves to be transient and reverses because the gas emboli are rapidly absorbed.

Maldistribution of ventilation–perfusion (V . / Q .) matching is the major factor leading to hypoxemia and changes in CO₂ concentrations.
With small amounts of continuous gas bubble infusion (0.2 mL/min/kg) into the venous circulation, there is an increase in high V / Q areas in the lung. With larger volume gas emboli (0.75 to 2 mL per kg), however, shunting and an increase in the physiologic dead space have been shown to occur and to increase proportionally as the volume of embolic gas increases. This effect can involve as much as 35% of the total cardiac output, and it may be severe enough to cause CO₂ retention in addition to hypoxemia.

The end-tidal CO₂ concentration (ETCO₂) decreases during VGE as a result of the increase in dead space caused by vascular obstruction. More simply, ETCO₂ decreases as CO₂ is “washed out” of alveoli that are ventilated but not perfused adequately. Inadequate matching may further worsen in the setting of a reduced cardiac output, resulting directly from VGE or indirectly as a consequence of non–embolic-related events (e.g., blood loss, myocardial ischemia, vasoactive medications). Any reduction in pulmonary blood flow decreases the delivery of CO₂ in the venous blood to the alveoli, thereby further decreasing the ETCO₂.

Paradoxic Embolism

A paradoxic embolism may occur in the presence of intrapulmonary arteriovenous anastomoses (IPAVA; owing to their larger diameter as compared with the general pulmonary microcirculation) or via an anatomic intracardiac shunt. A gas embolism may elevate right-sided heart pressures, thus facilitating right-to-left shunting through a patent foramen ovale (PFO). Autopsy studies of patients with no history of cardiac disease document the presence of a probe-patent PFO in 25% to 35% of the general population [1].

Considered an anatomic variant, a probe-patent PFO is generally 1 to 10 mm in diameter and remains functionally closed as long as left atrial (LA) pressure exceeds RA pressure. A reversal of the normal interatrial pressure gradient might be expected to increase the risk of paradoxic embolization. RA pressure has been demonstrated to be higher than LA pressure in the seated position in up to 54% of adult humans monitored during neurosurgical procedures [1]. The critical pressure necessary for gas bubbles to be forced through a PFO is not known, but it is likely to be small. After cardiac surgery, it has been shown that as little as a 4 mm Hg gradient can produce a 50% right-to-left intracardiac shunt [1].

Clinically, it may be important to distinguish between an anatomic PFO and a functional PFO because it is only the latter that has an impact on any morbidity and mortality experienced. It has been reported that paradoxic embolization occurs in only 15% to 25% of patients with a PFO [1]. Contrast echocardiography using agitated sterile saline given as a
rapid intravenous bolus has documented a lower prevalence of functional PFO (i.e., 10% to 20%) [1], as compared to the known prevalence of 25% to 35% for anatomic PFO. The amount of contrast material crossing from the right heart to the left heart does not correlate with the magnitude of shunt flow, nor does the Valsalva maneuver provoke shunting in all patients with PFO [1]. The question remains as to whether this finding represents a low sensitivity of this method for detecting PFO or whether there are some anatomic PFOs that have no functional role. Consensus opinion is that all PFOs should be considered to have the potential for allowing paradoxic embolization. Multiple reports have documented that the absence of any agitated saline or color flow through the interatrial septum by echocardiography does not exclude the presence of a PFO; it only excludes the presence of a right-to-left interatrial shunt at that moment in time [1].

Bubble passage through the pulmonary circulation has been shown to occur in the absence of intracardiac communications when the rate of venous air infusion exceeds the rate of pulmonary filtration and excretion [1]. Paradoxic air embolization during cardiopulmonary bypass has been reported to occur in the absence of an intracardiac defect when the mean PA pressure exceeds approximately 30 mm Hg [1]. Animal research suggests the existence of this same “critical value” of PA pressure that, once exceeded, dramatically increases the tendency for paradoxic embolization [1]. This increase occurs presumably on the basis of IPAVA (which may be as large as 500 μm in diameter), bronchopulmonary anastomoses (i.e., flow is from the PA to the bronchial veins and then to the pulmonary veins), or by routine transpulmonary passage of the gas across the capillary beds.

Factors Affecting Mortality

The size of the embolus, its rate of delivery, and the final destinations of the gaseous emboli are the most important factors influencing the severity of injury produced by VGE. Among humans, accidental bolus injections of 100 and 300 mL of air have been reported to be fatal [1]. In critically ill patients with minimal cardiopulmonary reserve, smaller emboli could be expected to have a greater morbidity.

In the context of equal volumes, mortality is decreased if the embolism is of CO\textsubscript{2} rather than air or O\textsubscript{2}. Animal work indicates that CO\textsubscript{2} may be injected to five times the volume of O\textsubscript{2} before symptoms of embolism appear, presumably because of its greater solubility in blood [1]. Although tolerated to a larger extent, it must be remembered that CO\textsubscript{2} emboli are not entirely benign and may lead to similar clinical consequences as air embolization.
When nitrous oxide (N₂O) is used for anesthesia, mortality is increased in the setting of VGE [1]. N₂O attains a high blood concentration because of its high solubility (approximately 20-fold that of O₂ and 34-fold that of N₂). Because a large concentration gradient would exist between this blood and any air embolus, N₂O would be expected to diffuse from the blood into the embolus. As a result, the embolus increases geometrically in size in direct relation to the partial pressure of N₂O because the N₂O molecules can diffuse from the blood into the air embolus much more rapidly than the N₂ can be removed. The end result is a potential worsening of any generated physiologic abnormalities or delay of the ultimate resolution of the embolus. The presence of N₂O in the anesthetic mixture has been shown to reduce the median lethal dose of a given volume of air by a factor of 3.4 [1].

Diagnosis

Clinical Manifestations

The symptoms of VGE are generally nonspecific. Patients may report feeling faint or dizzy, express a fear of impending doom, or even complain of dyspnea or substernal chest pain. This presentation, with or without paradoxic embolism, may mimic an acute cardiopulmonary or central nervous system (CNS) event. Severe VGE may present dramatically with elevated neck veins, “clear lungs,” and hypotension, and it may be rapidly followed by altered mental status and death. Because signs and symptoms are nonspecific, the importance of a detailed history, familiarity with the clinical situations in which VGE occurs, and a high degree of clinical suspicion cannot be overemphasized if one is to make an accurate diagnosis.

Physical Examination

Physical examination is usually not helpful for making the diagnosis. The only “specific” sign attributed to VGE is the classic mill-wheel murmur, otherwise reported only to occur in the rare syndrome of hydro pneumopericardium. This murmur has been described as the rhythmic splashing or churning sound generated by the agitation of gas trapped with fluid in a closed space. Most often, it is only audible
transiently and is heard infrequently at best, even with severe VGE. With large emboli and resultant cardiovascular collapse, a sound resembling the “squeezing of a wet sponge” has been described over the precordium [1]. VGE may occur without any change of vital signs. Wheezing as a result of acute bronchospasm may occasionally be heard. In a prospective study of seated neurosurgical patients, marked hypotension was noted in 78%, respiratory changes in 61%, and ventricular ectopy in 50% [1].

Laboratory Data

Abnormal results may include electrocardiogram (ECG) changes consistent with myocardial ischemia or acute cor pulmonale, premature ventricular contractions, and/or arterial blood gas findings of hypoxemia and hypercapnia.

Radiographic Findings

Chest radiography may verify the presence of VGE, but it should not be relied on for the diagnosis, especially in emergent situations. Air in the main PA is pathognomonic of pulmonary VGE, and it is recognized as a characteristic bell-shaped lucency in the distal main PA. This sign is seen very infrequently, especially in supine patients. Other patterns seen are focal upper lung zone oligemia, central PA dilation, and air in the systemic veins or the arterial circulation [1]. Pulmonary edema ranging from hilar haziness to generalized vascular redistribution may occur soon after VGE, and it usually persists for at least 16 to 24 hours [1]. Noncardiogenic pulmonary edema has been reported [1], is usually self-limited, and resolves over several days. Progression of noncardiogenic pulmonary edema to full-blown acute respiratory distress syndrome has also been described [1].

Ventilation–Perfusion Lung Scans

On V / Q imaging, VGE may produce patterns consistent with “high probability” for pulmonary venous thromboembolism. Prompt and complete resolution of these scintigraphic perfusion defects within 24 hours has been documented [1], and it is probably characteristic for VGE. In contrast, perfusion defects produced by venous thromboembolism resolve more slowly over a period of weeks to months and may not ever resolve completely. Areas of V / Q matching (i.e., “indeterminate probability”) may coexist with V / Q mismatches, and they are believed to represent reflex bronchoconstriction in conjunction with occlusion of the PA or its branches. The decreased ventilation is apparently because of
the release of bronchoconstricting agents, such as serotonin, from the occluded segments of the PA. This phenomenon is readily reversible within several hours if the PA occlusion is transient, and it is related to rapid resolution of the gaseous emboli.

Detection and Monitoring Method

Precordial Doppler monitoring is generally considered one of the more sensitive techniques for detecting emboli. Because a gas–blood interface is an excellent acoustic reflector, when an ultrasonographic beam strikes a moving gas bubble, a distinctive and characteristic artifact above the background flow signal is produced.

VGE may be missed by this technique owing to the position of the probe or completeness of the examination. False-positive reports of VGE may arise as a result of arrhythmia. The sound pattern induced by a junctional rhythm may easily mimic changes produced by VGE. With a junctional rhythm, cannon A waves may be present because of contraction of the RA against a closed tricuspid valve. The resultant turbulence in the RA is detected and confused for VGE.

Serial measurements of PA pressure can be a useful monitoring technique because even small emboli may produce significant increases in PA pressures. Major increases of PA pressure do not occur unless at least 10% of the vasculature is obstructed and the rise in PA pressure is roughly proportional to the size of the embolus. Finally, the likelihood of a paradoxical embolism increases above a mean PA pressure of 30 mm Hg, and serial monitoring would potentially allow the clinician a chance to prevent or minimize this complication [1].

ETCO$_2$ and N$_2$ levels fluctuate with VGE. Because these changes probably result primarily from significant mismatch of ventilation and perfusion, it would be anticipated that they would detect emboli later than Doppler techniques or changes in PA pressure and that they would be more likely to miss small emboli. Like PA pressure changes, however, variations in ETCO$_2$ stay abnormal longer, and they are more closely related to the volume of gas embolized [1]. Potential confounding factors exist that may also cause a reduction in ETCO$_2$ in the absence of a VGE-related event, and they include any set of circumstances that result in an acute decrease of cardiac output, increases of alveolar ventilation, or increases of physiologic dead space.

Consideration of the advantages and disadvantages of the available VGE detection technology suggests that a combination of transesophageal echocardiography or precordial Doppler ultrasonography with PA pressure, ETCO$_2$, or transcutaneous O$_2$ devices would provide the highest sensitivity, the quantitative determination, and
the best available physiologic response monitoring. Across the United States, use of ETCO$_2$ monitoring in combination with precordial Doppler ultrasonography has become the primary, if not the standard, approach for VGE detection perioperatively.

**Treatment**

Because a fatal outcome may occur long before any confirming diagnostic tests can be performed, treatment must be initiated promptly at the earliest suspicion of gas embolization. In combined retrospective and prospective analyses of seated neurosurgical procedures, a significant beneficial role was found for the use of routine precordial Doppler monitoring [1]. Before the advent of routine Doppler monitoring, VGE was clinically detected less often (5.7% before vs. 32% after), but the episodes noted had more severe sequelae. Once precordial Doppler monitoring became standard, the morbidity and mortality directly related to venous or arterial emboli was documented to be 0.5%. This improvement of event detection and reduction in the severity of VGE was ascribed to earlier recognition, allowing for earlier institution of therapy and prevention of further occurrences.

**Routine Treatment Measures**

Immediate measures should include identification of the site of gas entry and prevention of further gas entry, cessation or correction of exacerbating factors, administration of 100% O$_2$, and changing position to the left lateral decubitus position. For most patients, the site of gas entry is readily apparent. Failure to stop gas entry in a timely fashion may be fatal. If there is suspicion of a low central blood volume, volume should be rapidly repleted. Immediate cessation of delivery of N$_2$O and ventilating with 100% O$_2$ facilitates resolution of any gas emboli experienced during anesthesia with this agent.

Because air emboli are composed of approximately 79% N$_2$ and 21% O$_2$, any maneuver that rapidly increases the elimination of dissolved N$_2$ should decrease the size of the embolus. Administration of 100% O$_2$ achieves this goal by washing N$_2$ out of the alveoli and by creating a favorable gradient for N$_2$ to cross into the alveolus from the blood.

Placing patients in the left lateral decubitus position may facilitate
movement of any air obstructing the pulmonary outflow tract toward the apex of the RV, thereby relieving the obstruction and improving survival.

Aspiration and Dislodgement

For patients with witnessed gas embolism or in whom monitoring techniques suggest that the gas is still trapped in the heart, attempts can be made to aspirate or dislodge the gas. Gas may be aspirated from the heart by placing a central venous catheter into the RA or the RV or by pulling back a PA catheter and then aspirating serially from each successive heart chamber [1]. In unwitnessed gas embolism, this early phase has usually passed before the embolism is detected, and these interventions may result in more harm than benefit. Closed-chest compression may dislodge the embolus from the RV.

Hyperbaric Oxygen

When available, use of hyperbaric oxygen (HBO) may be helpful. HBO is the only therapy demonstrated to have any benefit well after VGE has been clinically established [1]. Even after emboli of 150 to 500 mL, HBO produced rapid improvement of all cardiopulmonary and neurologic abnormalities despite delays in initiating therapy of up to 20 hours. The most common HBO treatment protocols in use today are the US Navy Treatment Tables 5, 6, and 6A [2]. Use of these Tables is briefly discussed later in “Treatment” section of Decompression Sickness. Although it is accepted that HBO should be instituted as early as possible, the literature supports that special consideration be given to this modality at late stages, even in a seemingly irrecoverable situation [1,3].

Managing Unwitnessed Venous Gas Embolism

Given that VGE may mimic or cause a clinical presentation that is difficult to distinguish from venous pulmonary thromboembolism (PE), RV infarct, myocardial infarction (MI), or stroke, clinicians may frequently feel reluctant to consider the difficult to establish diagnosis of VGE and to begin treatment until other causes are ruled out. The simple measures indicated for the immediate management of VGE outlined herein are not contraindicated for the management of any of the other conditions typically in the differential diagnosis.

Little has been published on the clinical management of cardiovascular consequences of VGE. Because MI and RV infarct may frequently accompany large VGE, urgent, routine evaluation with ECG and echocardiography would be indicated for most cases. Because myocardial ischemia and subsequent MI of VGE probably result from hypoxemia, the
effects of massive overdistention of the ventricle, and perhaps direct embolization of coronary vessels, the value of traditional management techniques for MI is not clearly established. There are no theoretical contraindications to the use of nitrates, aspirin, β-blockers, calcium channel blockers, or vasodilators in patients with ECG changes. The role of anticoagulation or thrombolytic therapy in VGE is unclear.

Discrimination between PE and VGE in patients with unwitnessed, unmonitored events can be difficult. Patients at risk for VGE are frequently at risk for PE as well. Once the gas has left the RV, changes in PA pressures and ETCO$_2$ values may be similar in both conditions. As noted earlier, the radiologic findings may be similar, but they may resolve within 24 hours with VGE. If the clinical suspicion of PE is high, there is no known contraindication to initiating appropriate anticoagulation for patients with suspected VGE.

**Prevention**

Preventive measures are likely the most valuable management strategy for VGE. All patients undergoing the procedures listed in Table 177.1 [1] should be considered at high risk. In addition, hyperventilation, obstructive lung disease, and hypovolemia are common clinical conditions that increase the natural pressure gradient between atmospheric air and the central venous compartment; they may, therefore, also increase the chances of VGE during predisposing manipulations. Patients with a known PFO, pulmonary hypertension, previous MI with markedly reduced RV function, known right-to-left shunts, or congenital heart disease with any of the mentioned abnormalities should also be considered at high risk, not for experiencing an embolism per se but for being susceptible for increased morbidity and mortality of a paradoxic embolism. A high false-negative rate (sensitivity, 64%) limits the usefulness of preoperative transthoracic echocardiography with Valsalva maneuver in predicting the presence of PFO and the risk of paradoxic emboli [1].

In general, patients should have procedures performed in a supine rather than upright position, and the point of potential air entry should be kept lower than the RA. Placement, manipulation, and removal of subclavian and internal jugular venous catheters are probably the most common clinical procedures during which specific measures can be performed to prevent substantial air embolization [1]. All patients should be placed in the Trendelenburg position, and they should be asked to perform the Valsalva maneuver or to hold their breath during needle/wire/catheter insertion. The operator should completely occlude the hub of the needle during manipulations to prevent open communication with atmospheric pressure. During removal of central
catheters, patients should also be placed in the Trendelenburg position, the entry site should be compressed, and an occlusive dressing applied.
ARTERIAL GAS EMBOLISM

Arterial gas embolism (AGE) probably occurs daily in most hospitals owing to the prevalence of the situations known to be associated with AGE (Table 177.2) [1]. Although the prevalence of AGE is likely not as high as VGE, the clinical significance is potentially much greater than VGE (Fig. 177.1). In the clinical setting, most causes of AGE are preventable, and prompt treatment is frequently effective.

Etiology

**Cardiac Surgery and Bypass**

AGE during cardiopulmonary bypass has an estimated incidence that ranges from 0.1% to 11.0% [1]. There is evidence that the use of in line filters and preferential use of membrane oxygenators over bubble oxygenators may decrease this risk significantly.
The importance of trapped air in the left heart as a potential source of AGE after an open cardiotomy has been appreciated for years. Air may remain adherent to the endocardium, sutures, and prosthetic valves, and in cul-de-sacs in the atria, ventricles, or aorta even after the heart is closed and beating spontaneously again. Complete air evacuation, even after specific and meticulous venting techniques, is nearly impossible to achieve [1]. Residual air has been shown to be present in the heart after discontinuation of bypass in approximately two-thirds of patients undergoing open cardiotomies and in approximately 12% of patients undergoing coronary artery bypass grafting (CABG) only, for an overall incidence of approximately 45%. The source of intracardiac air resulting from CABG operations is thought to be because of the ascending aorta being cross-clamped and suction then being applied to the left heart or the aortic root for the purpose of venting. The resultant pressure decrease is transmitted to the coronary arterial circulation, thus allowing air entry via the coronary arteriotomy site, with subsequent passage into the aortic root or the left ventricle. Any gases trapped in a proximal coronary artery or in a distally attached vein graft may also pass into the aortic root in the absence of venting if the graft is injected under pressure, as occurs commonly during the administration of cardioplegic hypothermia.

Transcranial Doppler monitoring of the middle cerebral artery during open-heart operations has confirmed the occurrence of cerebral gas embolization [1]. With refined surgical techniques, over time there has been a considerable reduction in the incidence of major neurologic injury after cardiac surgery and CABG, with a currently reported incidence of approximately 5% to 10% [1]. Detailed neuropsychiatric function testing, however, has shown persistent impairment of cerebral function in up to 70% of patients after CABG [1].

**Lung Trauma**

Systemic AGE is a frequent and unrecognized cause of death among patients with blunt or penetrating lung trauma [1]. The mode of air entry after percutaneous lung puncture, penetrating or blunt lung trauma, or with positive-pressure mechanical ventilation is via production of a bronchovenous fistula. Risk factors enhancing the chance of AGE include underlying emphysema, uncooperative patients, sneezing or coughing bouts, use of large diameter needles, hypotension, hypovolemia, Valsalva maneuver, and a site of involvement that is in close proximity to the hila. For patients with preexisting pulmonary fibrosis, one should expect an increased frequency and severity of systemic embolism because of the inability of the injured veins to retract and constrict. What has been referred to in the past as “pleural shock” (i.e., fainting, seizures, or even sudden death during a thoracentesis or therapeutic pneumothorax for
treatment of tuberculosis) has since become recognized as a manifestation of AGE. Percutaneous procedures with needle calibers less than 20G (0.9 mm) have generally been considered safe, despite a case report describing a cerebral AGE after transthoracic aspiration with a 23G (0.6-mm) needle. The reported incidence for this complication for needles of 16G to 20G (0.9 to 1.6 mm) has been variably estimated at 0.5 to 0.8 in 1,000 cases [1].

Arterial Lines

Cerebral AGE via retrograde flow from an indwelling radial arterial line has been reported as a case study and then followed up with a laboratory investigation [1]. Radioactive xenon mixed with 2 to 5 mL of air and injected at a rate of 0.6 to 2.5 mL per second into the radial artery resulted in demonstrable retrograde passage into the cerebral circulation. This low-flow rate is approximately 5- to 25-fold less than the reported “safe range” of previous work [1]. Because the true “safe” amount of air that can remain in an arterial flush catheter without the risk of retrograde embolization remains unknown, medical personnel need to be vigilant and meticulous in ensuring removal of any entrapped air in arterial flush lines.

Percutaneous Transluminal Coronary Angioplasty/Coronary Artery Stents

Most coronary artery gas emboli resulting from percutaneous transluminal coronary angioplasty or stenting of a coronary artery are reportedly extremely small, and they do not result in symptoms or hemodynamic consequences [1]. Of the symptomatic episodes, most cause rapid onset of chest pain with ECG evidence of ischemia or infarction. The systemic blood pressure may be unaffected, or it may be mildly decreased. For almost all patients, these effects resolve spontaneously within 5 to 10 minutes, similar to findings from experimental models. Only rarely does percutaneous transluminal coronary angioplasty–related AGE result in bradycardia, hypotension, ventricular fibrillation, MI, or asystole [1].

Pathophysiology

In AGE, the gas enters the arterial system by the direct rupture of a
blood–air interface, by direct passage from the PA to pulmonary venous system, or through a functional right-to-left cardiac shunt. Gas bubbles distribute themselves throughout the body primarily directed by the relative blood flow at the time. Bubble buoyancy is actually a minor factor unless there is a significant depression of forward systemic flow [1]. Because the heart, lung, and brain receive the greatest amount of blood flow, the consequences of embolization are most frequently reported for these organs. Pulmonary manifestations of AGE are uncommon, perhaps because the redundancy of the pulmonary vascular supply limits the consequences of bubble occlusion.

Systemic Mechanical and Biophysical Effects

Bubble formation results in two broad categories of effects: mechanical—physical obstruction to blood flow with distortion or tearing of tissues as the bubble forms and expands, and biophysical—where the blood–gas, blood–tissue, or gas–endothelial interfaces stimulate a cascade of leukocyte, platelet, coagulation, fibrinolytic, and complement-mediated activations [1]. Research over the last few decades now recognizes the importance of oxidative stressors causing impairment of endothelium-dependent vasorelaxation (i.e., the endothelial dysfunction hypothesis). This is primarily caused by loss of nitric oxide activity in the vessel wall [1,3,4].

Similar to VGE, the trapped bubbles may pass through the circulation and exit via the lungs, or they may be slowly metabolized by body tissues. Unlike the situation when bubbles are trapped in a vein, an arterial occlusion may have an immediate clinical impact. Uptake and release of inert gas by a particular tissue depends on the rate of blood flow to that tissue, as well as the rate of gas diffusion out of the blood into the tissue.

When bubbles do form, the inert gas becomes isolated from the circulation, and it cannot be removed by blood flow until it diffuses back into tissues. The speed of diffusion is the result of the difference between the N\textsubscript{2} partial pressure in the air bubble and the N\textsubscript{2} partial pressure in the tissue. The partial pressure of the inert gas in the bubble also varies directly with the bubble’s loss of O\textsubscript{2} through metabolic conversion into CO\textsubscript{2}, which is 21 times more soluble than O\textsubscript{2}.

Cardiovascular Effects

The heart is extremely intolerant of even minute amounts of arterial gas. AGE may produce MI, loss of left ventricular function, dysrhythmias, hypotension, or hypertension. As little as 0.025 to 0.05 mL of air directly entering a coronary artery may result in transient impairment of
ventricular function, focal MI, ventricular fibrillation, or death [1].

**Central Nervous System Effects**

Cerebral embolism produces stroke-like symptoms and cerebral edema. Injury is probably more a result of damage from endothelial mediators, oxidant stress, and neuronal hypoxia rather than being directly a result of vascular obstruction or edema. After 5 to 30 seconds of arrested cerebral blood flow, most gas bubbles easily pass through the pial arteries. Significant volumes of gas may subsequently be collected in “air traps” in the jugular veins [1]. Larger emboli (e.g., large enough to obstruct several generations of arteriolar branching) are also generally only temporarily obstructing, and they relocate to the cerebral and the jugular veins during the period of reactive hyperemia that follows periods of arrested cerebral blood flow. Cerebral air emboli have been shown to persist in the circulation for 40 hours after initial insult [5]. It has been proposed, therefore, that the CNS dysfunction that follows cerebral AGE is not the result of bubble entrapment alone; it is instead, in large part, caused by effects on vascular endothelium or blood components.

**Diagnosis**

AGE, whether traumatic, iatrogenic, or dysbaric (i.e., solely as a result of changes in ambient pressures) in origin, presents immediately after the insult occurs, typically within 10 minutes. A myriad array of dramatic manifestations is possible, typically with symptoms suggestive of coronary or CNS involvement. If pain is the only symptom, however, AGE is unlikely. Two general clinical patterns have been recognized: fulminant collapse and isolated CNS injury. In the former, the initial presentation is apnea, coma, and cardiac arrest. This pattern is known to occur in 4% to 5% of patients with dysbaric air embolism but has an unknown incidence for other types of AGE. The responsible mechanism is believed to be direct coronary artery embolization with resultant MI or gaseous embolization of the cerebral circulation, resulting in hypertension and marked dysrhythmias. This subgroup is generally unresponsive to resuscitative efforts (Fig. 177.1).
Fatal air embolism after massive facial trauma and prolonged extrication in an unbelted, backseat passenger in a car accident. A: Cross section of the chest showing air outlining the right superior pulmonary vein (black arrow) emptying into the LA. Black* indicates the bronchus intermedius. B: Coronal reconstruction showing a massive air collection in the LA. LA, left atrium.

In the latter group, the initial presentation is that of stable respiratory and heart rates, but with a wide spectrum of neurologic signs and symptoms. Usually, the symptoms are abrupt in onset, and they progress rapidly to overt signs. Patients may feel faint or dizzy or have an apprehensive fear of death. There may be loss of consciousness, convulsions, visual disturbances (including blindness), headache, confusion or other mental status changes, coma, vertigo, nystagmus, aphasia, sensory disturbances, weakness or hemiparesis, or even focal or more widespread paralysis. The pupils are usually dilated, and, occasionally, air may be seen in the retinal vessels. Liebermeister’s sign may be present and is recognized as sharply defined areas of tongue pallor. Marbling of the skin of the uppermost portions of the body is another pathognomonic sign of AGE (along with retinal gas and Liebermeister’s sign) [1]. With prompt recompression therapy, the majority of these cases have the potential for full recovery.

Other clinical manifestations of extra-alveolar gas are related to the traumatic entry of air into the interstitium after alveoli rupture. The air may dissect along the perivascular sheaths into the mediastinum, causing pneumomediastinum, usually associated with a substernal aching or tightness that may have a pleuritic nature and may radiate to the neck, back, or shoulders. There may be coexistent subcutaneous emphysema and a notable “crunching” sound with each heartbeat (Hamman’s sign).
caused by air in the pericardium. Air may dissect further to cause a pneumothorax in up to 10% of cases [1]. Tension pneumothorax may occur in patients on positive-pressure mechanical ventilation or during decompression. Pneumopericardium and air in the retroperitoneum and subcutaneous tissues of the neck, trunk, or limbs may also occur. This extra-alveolar gas also has access to torn pulmonary blood vessels when the intrathoracic pressure decreases during normal inspiration after barotrauma has occurred. Once egress into the pulmonary venous circulation has occurred, migration to the left side of the heart and then to the arterial circulation may follow. Hemoptysis has often been mentioned as a cardinal sign of dysbaric air embolism, but it actually occurs in a minority (approximately 5%) of patients [1].

**Treatment**

Management of AGE and decompression sickness (DCS) is similar. Appropriate therapy involves prompt recognition, initial stabilization (with emphasis on preventing further damage), and definitive specific therapy (Table 177.3). All patients undergoing cardiopulmonary procedures or with recent lung trauma must be considered at high risk for AGE. Therefore, it cannot be emphasized strongly enough that a high index of suspicion for these diagnoses is one of the most important elements of care. Like many other true medical emergencies, therapeutic interventions should not be delayed to implement diagnostic testing. Details of therapy are found in the next section.

**TABLE 177.3** Treatment Summary of Arterial Gas Embolism and Decompression Sickness

- Of time-tested benefit
  - Prevent further bubble formation and extension of other injuries
  - Cardiopulmonary life support as needed
  - 100% concentration of inspired oxygen
  - Maintain intravascular volume with isotonic fluids
  - Treat coexisting problems
  - Transport as soon as possible to recompression facility
  - Hyperbaric therapy
- Unproven benefit (but generally believed to be helpful)
  - Supine position (avoid head-down
Avoid glucose-containing infusions
Avoid hypertension, anxiety, hyperthermia
Lidocaine for the treatment of AGE
Diazepam for seizures, severe agitation, intractable vomiting (not used prophylactically)
DVT prophylaxis for patients with lower extremity weakness/paralysis.
Experimental or of questionable benefit
Antiplatelet agents
Corticosteroids (possible central nervous system toxicity)
Calcium channel blockers
Lidocaine in the treatment of DCS
Combination nonsteroidal anti-inflammatory drug, heparin, and prostaglandin I2
Perfluorochemicals and/or other surface-active agents
Induced hypothermia
Cerebral venoarterial perfusion
Proven detrimental
Recompression while submerged (used only as a last resort)
Alcohol/analgesics
Volume overload in AGE or with cardiopulmonary symptoms
Delayed transport to hyperbaric oxygen facility
Additional hypobaric exposures

AGE, arterial gas embolism; DVT, deep venous thrombosis; DCS, decompression sickness.
DECOMPRESSION SICKNESS

DCS occurs only when a transition is made to an environment with a relatively lower ambient pressure. Any rapid lowering of ambient pressure, regardless of the initial pressure level or saturation of inert gas, results in the release of bubbles of inert gas into the blood and tissues. This is equally true for too quick a return to a normobaric state after a hyperbaric exposure (as in diving or compressed air mining), or for rapid progression from a normobaric state into a hypobaric exposure (as in aviators, astronauts, or mountain climbers). It is estimated that around 10 million divers are currently active worldwide, performing more than 250 million dives annually and that at least 1 in 20 divers will experience DCS in their diving careers [6]. Statistics compiled by the Divers Alert Network (www.diversalertnetwork.org) indicate that there are more than 1,000 diving-related injuries annually in the United States alone, of which nearly 10% to 15% are fatal. DCS is the most frequent serious complication of self-contained underwater breathing apparatus (scuba) diving with an overall incidence of 1 to 35 cases per 10,000 dives [1,6,7] depending on the region of the world and the type of diving involved. DCS ranks third, after drowning and barotrauma/AGE (estimated incidence of 7 cases per 100,000 dives), as a cause of death among divers [1,6]. Strict enforcement of work regulations for tunnel workers and pilots has greatly decreased the incidence of DCS in these two groups. Interestingly and for unknown reasons, in hypobaric-related DCS, symptoms of spinal cord involvement are less common, whereas symptoms of brain involvement are more frequent as compared with hyperbaric-related DCS.

Etiology

Diving

The turn of the 20th century saw the origin of decompression tables, which define set depths and time limits of hyperbaric exposure to be used by divers to minimize the risk of DCS. Although derived empirically by J. S. Haldane, all common schedules since have been based on his original methods. Haldane’s work demonstrated that the human body could tolerate a twofold reduction in ambient pressure without symptoms of DCS. Haldane also formulated the concept that the tissues of the body absorb nitrogen at varying rates, depending on the type of tissue and its vascularity. It is important to remember that dive tables are not infallible, and DCS may still occur despite following a “no decompression” profile.
Experience has shown that modern scuba divers and aviators can have a significant net accumulation of inert gas (VGE) and yet remain without symptoms [1,8]. There is an important inter- and intraindividual variation in the degree of “bubbling” after a dive, indicating a significant, but as yet poorly characterized, influence of personal factors affecting gas saturation and desaturation [1,8].

**Flying**

DCS because of rapid hypobaric exposures is a syndrome indistinguishable from that produced in divers, and it is usually the result of accidental loss of cabin pressure in a pressurized aircraft. The altitude threshold for DCS is generally reported to be approximately 18,000 ft., but unless a person has had a hyperbaric exposure within the past 24 hours, there are rarely any difficulties with exposure to altitudes of up to 25,000 ft. [1]. Exposures above this level up to approximately 48,000 ft. for durations of 30 minutes to 3 hours have resulted in a DCS incidence of 1.5% [1]. More prolonged exposures and even greater altitudes increase the severity of an episode of DCS. Modern airline transportation has minimized these risks by pressurizing aircraft to maintain cabin pressures equivalent to 8,000 ft. while flying at actual altitudes of greater than 40,000 ft. DCS may also occur while flying after a diving trip, and it may be produced by exposure to altitudes of as little as 4,000 ft., even when “no-decompression” type of diving took place. Current recommendations are to avoid all flying for at least 12 hours after any dive. For flights exceeding a cabin pressure equivalent of approximately 8,000 ft., or for the case of divers requiring decompression stops, at least a 24-hour delay is recommended before flying.

At the extreme of human hypobaric exposures is the astronaut. Astronauts performing activities outside their space vehicles are decompressed from a cabin pressure equivalent to sea level, down to a suit pressure equivalent of approximately 30,000 ft. [1]. To minimize the risk of DCS, astronauts breathe 100% O₂ before decompression (“prebreathing”) to reduce the partial pressure of N₂ before entering the space-suit environment. Only time and further space exploration will elucidate the risks of DCS from these types of exposures [9].

**Pathophysiology**
Bubble Formation

During DCS, the gas previously dissolved in body tissues and blood is released as gas bubbles into the tissues and the bloodstream. Boyle’s law states that the volume of a gas varies inversely with its surrounding absolute pressure. At sea level, the weight of air that we breathe is equal to 14.7 lb per square in, 760 mm Hg, or 1 atmosphere absolute (ATA), depending on the choice of units. Table 177.4 indicates that for every 33 ft. of seawater a diver descends, the ambient pressure increases by 1 ATA and that the volume occupied by that same gas decreases proportionally. This table also demonstrates the reduction of pressure and volume expansion that accompanies increases of altitude.

The gear divers use to allow them to breathe underwater is designed to deliver air at the ambient pressure of the surrounding water, allowing the diver’s lungs to remain fully expanded. As a scuba diver ascends slowly from depth, pressure in the lungs equalizes with ambient pressure as long as proper exhalation is achieved. If, for some reason, these expanding
gases are not allowed to escape from the lungs (e.g., breath holding, localized gas trapping), overdistention of the alveoli may occur, which can result in pulmonary barotrauma. The fragility of alveoli is not generally appreciated, but it is highlighted by the fact that with the lungs fully expanded on compressed air, a pressure differential of only 95 to 110 cm H$_2$O (equivalent to an ascent from a depth of only 4 to 6 ft.) may be sufficient to rupture alveolar architecture [1]. With very few exceptions, all scuba diving is done at pressures less than 7 ATA, and most is done in the 2 to 4 ATA range [1,6].

Dalton’s law of partial pressures states that the total pressure exerted by a mixture of gases is equal to the sum of the partial pressures of its constituent gases. The composition of gases that make up our atmosphere remains essentially constant up through an altitude of approximately 70,000 ft.: 78.08% N$_2$, 20.95% O$_2$, and the remaining fraction of CO$_2$, hydrogen, helium, argon, and neon [1]. In most settings, N$_2$ is the predominant constituent of any inhaled gas mixture. N$_2$ is inert (i.e., it is unused/unchanged by passage through the body). This fact is in contrast to CO$_2$ and O$_2$, which are actively transported and, therefore, do not depend entirely on purely physical laws for removal. N$_2$ is more soluble in fat than in water, which suggests that during decompression, bubbles more likely form in lipophilic tissues such as bone marrow, fat, and spinal cord.

Henry’s law of gas solubility states that the amount of gas that dissolves in a fluid is directly proportional to the pressure of that gas on that fluid. The deeper one descends underground or in the ocean, the greater the driving pressure for the gas on the blood and the bodily fluids. The total accumulation of dissolved N$_2$ into the tissues of the body, therefore, depends on the depth achieved and the time spent at that depth. As ambient pressure decreases on ascent, solubility decreases and gas is released from body fluids.

Studies of bubble formation suggest that of the total absorption of inert gas that occurs during a dive, only 5% to 10% is released as bubbles after a rapid decompression [1]. The site of origin of intravascular bubbles is controversial, but overwhelming human and animal experimental evidence shows that gas bubbles are first detected in the venous circulation during decompression. Whereas the inability to detect venous bubbles is a good predictor of safety from developing DCS (NPV 99%), the occurrence of venous bubbles (even high grade) is a poor predictor of
DCS (PPV 4%) [4]. It is most probable that AGE in DCS arises from the venous circulation or from pulmonary barotrauma with entry of gas bubbles into the pulmonary veins (i.e., dysbaric air embolism). Biophysical effects result from the blood–gas, blood–tissue, and gas–endothelial interfaces, where an enormous chemical and physical discontinuity activates and amplifies reactive systems that are usually quiescent during normal blood flow. Electrochemical forces also exist at any blood-damaged endothelial interfaces, and they activate coagulation, complement, kinin, and fibrinolytic systems and allow for the denaturation of proteins. During DCS, and presumably with AGE, a localized hypercoagulable state develops, with a coexistent reduction in platelet count because of aggregation at the blood–bubble interface with leukocytes, red blood cells, and formed fibrin strands. The end result of this diffuse activation is to amplify any existing mechanical obstruction to blood flow with progressive sludging and clotting [1]. Further tissue injury then results from a decrease of local blood flow, edema formation, leukocyte chemotaxis, and oxidant stress. Newer studies also suggest impaired endothelial function owing to altered nitric oxide (NO) production or availability may play a significant role in the formation of vascular bubbles [4]. These effects are likely to be most important among cases of CNS involvement, for which small areas of reduced blood flow can produce severe disability or death. A disturbance of barrier function would best account for the well-established features of AGE and DCS which are otherwise difficult to reconcile with simple vascular occlusion as the sole explanatory mechanism.

It is important to emphasize that divers perform safe decompressions millions of times each year. For most, this process involves only a slow ascent after a short-duration dive. Others may require staged ascents, with one or more stops at intermediate depths to give more time for N₂ elimination. Still others require planned periods of chamber recompression after diving to prevent DCS. The overall safety of decompression exposures has withstood the test of time, and it has improved with experience and use of preventive measures. Safe decompression is by far the rule, rather than the exception.

**Diagnosis**

The clinical manifestations of DCS are protean, reflecting the effects of bubbles distorting tissues, obstructing blood flow, and perhaps, most importantly, by endothelial activation and initiation of oxidant stress and a pro-inflammatory response. Symptoms will generally occur within 1 hour of a decompression event among approximately 42%, and within 8 hours for over 80% of afflicted individuals [2]. A gross classification system is in common use based on the perceived severity of the clinical
situation and the anticipated response to therapy. Type I DCS encompasses 75% to 90% of patients and includes those with musculoskeletal pain; skin or lymphatic manifestations; or nonspecific symptoms of anorexia, malaise, and fatigue. Generally, these patients require only a brief period of repressurization. Caution is still in order because up to 20% to 30% of this group may progress to a type II illness. Type II DCS is characterized by those cases with CNS or peripheral nerve involvement or any cardiorespiratory dysfunction. Overall, 10% to 25% of patients have type II DCS, and it generally represents a more severe illness with the potential for greater difficulties during treatment. The presence of a PFO is associated with a four- to sixfold increase in the odds ratio of developing a type II DCS [1,10–13].

Type I Decompression Sickness

Type I DCS includes the most common and classic manifestations usually associated with DCS. The majority of patients report a deep, dull “aching” pain in a limb during decompression or within the first 36 hours after surfacing (98% of patients experience onset within 24 hours of surfacing). Initially, there may be a vague feeling that “something is wrong,” and the limb discomfort is dull and poorly localized. With time, this may progress to an intense throbbing pain within a more circumscribed and specific location. The affected area is generally nontender to palpation, and movement of any affected joints does not exacerbate the pain, except among severe cases.

The limbs are the most common sites of symptoms of DCS (in approximately 92% of cases of DCS overall and as the initial clinical manifestations of DCS in approximately 77%) [1,6]. Shoulders, elbows, and knees are the most commonly affected joints. More than one site may be involved, but rarely is the distribution bilaterally symmetric. Any pain occurring in the abdominal or thoracic areas, including the hips, should be considered a symptom arising from spinal cord involvement and treated instead as type II DCS. Heat, ice, immobilization, and potent analgesics do not relieve the pain, which is caused by the collections of gas in the periarticular and perivascular tissues. The most striking characteristic of this pain is its rapid relief with recompression. This rapid relief of discomfort with the application of pressure, and especially the tendency for this pain to return to the same site if recompression is inadequate, distinguishes the pain of “the bends” from any coexistent musculoskeletal strain or from the ischemic pain resulting from AGE.

Usually, there are no objective physical signs associated with limb DCS, except for a potential “peau d’orange” appearance of the skin from local lymphatic obstruction. The skin exhibits two distinct types of manifestations of DCS: (a) a transient pruritus involving ears, trunk,
wrist, and hands (more common after exposure in hyperbaric chambers) and (b) a more intense itching, usually limited to the trunk, that begins as erythema (from dermal vasodilation) and progresses to a characteristic mottling with confluent rings of pallor surrounding areas of cyanosis. This lesion blanches to the touch and is known as cutis marmorate. These changes are thought to result from bubble obstruction of the skin’s venous drainage or bubble-induced vasospasm [1]. These abnormalities generally resolve spontaneously over a few days. Importantly, cutis marmorate is considered a manifestation of type II DCS and treated as such.

**Type II Decompression Sickness**

Type II DCS may occur separately or in combination with the musculoskeletal pain of type I DCS in up to 30% of patients [1,2,6]. The primary organ systems affected in this category are pulmonary, nervous, and vestibular.

Pulmonary DCS, known as “the chokes,” occurs rarely in diving (approximately 2% of the overall cases [1]), and it is generally the result of very rapid or emergency-type ascents. Aviators, astronauts, and submarine trainees are also in situations in which sudden dramatic decompression may occur, and pulmonary DCS has been noted in nearly 6% in these groups [1]. Clinically, this condition usually begins with a substernal discomfort that starts within minutes of reaching the surface. As it progresses, the discomfort may take on a respirophasic nature. The respiratory pattern becomes more rapid and shallow, with occasional paroxysms of a nonproductive cough. Evidence of right heart strain or failure may develop and may progress to full-blown cardiovascular collapse. The underlying mechanism involves both direct and indirect effects of massive pulmonary gas embolization from VGE.

Neurologic DCS has a varied incidence among different populations [1]. A wide range of possible presenting signs and symptoms may be produced by neurologic DCS, and all must be taken seriously even when there are no objective findings on neurologic examination. The spectrum of neurologic dysfunction ranges from pruritus with skin rash or “pins and needles” sensation (15% of cases) to full paralysis (6%) or convulsions (1%) and death. Personality changes and agitation occur in 3%, but they are very rarely the presenting symptoms. Visual disturbances (7%) and difficulties with cerebellar function (18%) are also frequently seen. The pathogenesis underlying CNS injury from DCS is the
subject of much debate and controversy. Most researchers would agree that the notion of CNS tissue ischemia arising from obstructing arterial gas bubbles is too simplistic. As mentioned previously, the endothelial dysfunction hypothesis is currently under investigation as a better candidate mechanism to explain the varied manifestations of DCS.

Vestibular DCS, “the staggers,” occurs relatively commonly as the initial manifestation of DCS, and it comprises a syndrome of nausea, vomiting, dizziness, and nystagmus. Frequently, tinnitus or hearing loss may also be present. Typical onset is immediately after decompression, and it occurs in 13% to 72% of patients with type II DCS. The underlying pathology has been demonstrated in animals to be the result of rupture of the fragile membranes in the cochlea and semicircular canals.

Treatment

Prompt Recognition and Diagnosis

The most common problem in DCS and AGE is making the initial diagnosis. Particularly in the case of DCS, there is an early tendency by patients for denial of the existence of any problems. Any neurologic or cardiorespiratory symptoms after diving must be assumed to relate to AGE or DCS until proven otherwise.

Stabilization

Nonspecific therapy may help to stabilize the patient and prevent an extension of injury. Immediate institution of cardiopulmonary resuscitation may be needed, and it takes precedence over all other measures. Endotracheal intubation is sometimes necessary to ensure patency and protection of the airway. All balloon cuffs (endotracheal and Foley) should be inflated with sterile water rather than air to minimize the volume changes of these compartments during recompression therapy.

When AGE is suspected, most authorities recommend the flat, supine position initially. If the patient is unconscious or vomiting, the left lateral decubitus (Durant) position is also recommended. The Trendelenburg position is no longer advocated with the concern that maintaining this body position for extended periods may worsen any associated cerebral edema, and the knowledge that keeping the head lower than the heart does not prevent migration of bubbles into the cerebral circulation unless the patient is in total circulatory arrest or an extremely low-output state [1].

Once any life-threatening concerns have been addressed,
administration of 100% O₂ and the maintenance of intravascular volume become the next most important features of treatment while arranging transport to a hyperbaric facility. The 100% O₂ can be delivered intermittently or continuously for extended periods (generally up to 12 hours) without serious concern for any resulting significant pulmonary toxicity. The high fraction of inspired O₂ is used to alleviate any tissue hypoxia and to provide a strong concentration gradient that will wash out as much inert gas as rapidly as possible. Note that if the symptoms of AGE or DCS resolve or are improved after breathing 100% O₂, the patient will still require recompression therapy.

As a result of capillary endothelial injury, the more severe the DCS syndrome, the greater the magnitude of plasma leakage from the vascular space, the reduction in blood volume, and the resultant hemoconcentration [1]. Increased blood viscosity resulting from hemoconcentration may further impair any compromised microcirculation; therefore, normovolemia should be the goal of infusion therapy. Fluids should be administered to all individuals suffering from DCS except for cardiopulmonary DCS (“the chokes”) owing to concerns for exacerbating any pulmonary edema injury. In addition, because patients who suffer AGE are typically less dehydrated than those with DCS and because CNS injury in AGE may be complicated by cerebral edema, care should be taken not to overload the patient with AGE. Intravascular volume maintenance can be achieved with isotonic fluids given at a rate sufficient to keep the urine output at 0.5 to 1 mL/kg/h or more, and is recommended for patients who are vomiting, unconscious, or having any symptoms more severe than isolated limb bends. Glucose-containing solutions are probably best avoided in the first 12 hours after suspected cerebral embolization because an increased serum glucose level is one of the major determinants of the brain’s lactate production, which has been associated with increased neuronal damage in the ischemic state [1]. Conscious patients may be given judicious amounts of oral liquids, such as nonacidic fruit juices or balanced electrolyte solutions. Alcohol-containing beverages should be strictly avoided.

When the diagnosis of cerebral air embolism is evident on clinical grounds, comprehensive diagnostic testing is not necessary. Diagnostic testing should never delay transport to a facility equipped to provide HBO therapy or initiation of this specific therapy. If HBO is not immediately available, a noncontrast head computed tomography scan, chest radiography, and an ECG should be obtained while awaiting transport. For coma as a result of AGE or DCS, the head computed tomography will typically reveal multiple, small, well-defined, low-density areas in the brain. Head computed tomography scanning is also useful in ruling out possible correctable causes of intracerebral bleeding.
Magnetic resonance imaging and single-photon emission tomography techniques, where available, are likewise potentially useful to document the presence of cerebral gas collections. Because these tests are highly insensitive, negative studies alone should never deny patients’ access to HBO therapy in the appropriate clinical situation.

Patient Transport

When air evacuation is necessary to transfer a patient to a recompression facility, it is of utmost importance that the patient not be exposed to any further decreases in barometric pressure, as occurs with travel at increasing altitudes. In general, unless the aircraft is capable of maintaining a cabin pressure equivalent to sea-level pressure, flight altitude should not exceed 500 to 1,000 ft. above the departure point because deaths have resulted from exposure to altitudes of only 4,000 to 5,000 ft. [1,14]. It is believed to be preferable to await the arrival of a pressurized transport than to risk exposing a patient with DCS or AGE to further hypobaric insult.

To obtain a listing of the nearest recompression facility as well as advice on treatment options from a medical diving specialist on a 24-hour emergency basis, contact the Divers Alert Network Emergency Hotline at Duke University at (919) 684-9111. For nonemergency questions during regular business hours, contact the DAN Medical Information Line at (919) 684-2948.

Adjunctive Therapy

To date, other than supplemental O₂, there are no drugs of proven benefit for treating DCS or AGE. There is an unfortunate paucity of randomized controlled trials to guide treatment options. Several agents are used frequently, but this therapy is primarily based on expert opinion and limited trials involving small numbers of animal and human subjects [1,15]. For a discussion of the use of oxygen and fluids, see “Stabilization” section. As noted previously, there are some small but important differences in the recommendations for adjunctive therapies between AGE and DCS, and these will be briefly addressed below.

Steroids. Steroids are no longer recommended for the treatment of AGE or DCS.

Lidocaine. Lidocaine is not currently recommended for the treatment
of any type of DCS. Clinical evidence does support its use for the
treatment of AGE (reduces cerebral metabolism and stabilizes neural
membranes by decreasing the flux of sodium and potassium) [2].
Lidocaine may be given as a 0.5 to 1 mg per kg intravenous bolus at a rate
of 25 to 50 mg per minute, followed by 0.5 mg per kg intravenously every
5 to 10 minutes as needed, to a maximum total of 225 mg or 3 mg per kg,
whichever is lower. Patients with hypotension, cardiac arrest, or
biventricular heart failure should receive only a single loading dose of 100
mg. After the loading doses, a continuous intravenous infusion at 2 to 4
mg per minute may be used to achieve and maintain a blood level of 2 to
4 μg per mL. If an intravenous infusion cannot be established,
intramuscular administration of 4 to 5 mg per kg will typically produce
therapeutic plasma concentrations within 15 minutes and lasting for
approximately 90 minutes. Supratherapeutic doses may be associated
with paresthesias, ataxia, and seizures.

**Diazepam.** Intravenous diazepam is effective in the control of seizures,
severe agitation, and the intractable vomiting resulting from “the
stagger.” The typical regimen is a 5-mg intravenous bolus given over 3
minutes and then repeated every 5 minutes as needed (maximum dose,
20 to 30 mg) to control seizures. If intravenous access is not available,
the intravenous preparation may be given rectally to adults in a dose of
7.5 to 10 mg every 5 minutes as needed. Diazepam is not recommended
for use prophylactically in AGE or DCS because of its sedative properties
and its propensity to mask the onset of CNS toxicity, thus affecting the
ability to assess response to hyperbaric treatment. Generalized seizures
unresponsive to benzodiazepine therapy may be suppressed with
barbiturates [1,15].

**Anticoagulants.** Anticoagulants should not be used routinely in the
treatment of AGE or DCS. The exception to this is the patient suffering
from lower extremity weakness or paralysis. In these cases, low molecular
weight heparin should be initiated as soon as possible after injury to
reduce the risk of deep venous thrombosis (DVT) and pulmonary
embolism. Enoxaparin 30 mg, or its equivalent, is given subcutaneously
every 12 hours. Intermittent pneumatic compression is an alternative
although less effective for preventing DVT [2].

**Aspirin and other Nonsteroidal Anti-inflammatory.** Routine
use of agents with antiplatelet effects is not recommended in AGE or DCS
owing to concerns for worsening any neurologic hemorrhage.

**Antipyretic Therapies.** Any AGE or DCS with evidence of brain or
spinal cord injury should receive aggressive treatment for elevated body
temperature to prevent further neurologic insult [2].

Until further studies are performed, discretionary therapy with these
adjunctive agents should be considered the realm of “clinical judgment” and “expert opinion.” Evidence-based recommendations await results from further controlled trials.

**Hyperbaric Therapy**

Hyperbaric therapy involves exposing the entire body to prolonged periods of higher than atmospheric pressure; it specifically treats AGE and DCS [1,2,16]. Anecdotal reports of success in isobarically occurring AGE lends credence to the recommendation for early consideration of HBO therapy for any suspected cerebral gas embolism [1]. Many treatment protocols have been proposed [17,18], and none would be expected to be fully efficacious and life sustaining for all cases. As of 2015, no randomized controlled human studies exist that compare these different treatment options. A review of the pertinent literature on humans since the 1960s reveals a decrease in cerebral air embolism mortality from 93% for those not receiving therapy to 28% to 33% with closed-chest massage and “conventional therapy,” and then to 7% with addition of HBO [1], and would seem to argue strongly for this modality for AGE.

Fully 80% to 90% of all patients with DCS or AGE effectively respond to recompression therapy [1,6,18]. Although there is generally an inverse relationship between any delay to treatment and complete symptom resolution, evidence supports the use of HBO for AGE and DCS even after delays of more than 24 hours. Delays of initiating recompression therapy for up to 10 days have been anecdotally reported in the literature to be successful in up to 90% of these patients [1]. Recompression treatments may be repeated as needed until symptoms resolve entirely or until improvement reaches a plateau and there is no further improvement [2,6]. Approximately 40% of injured divers show complete resolution after the first treatment, and only 20% require more than three rounds of recompression therapy [2,6].

The mechanism of action of HBO therapy involves a decrease in volume of any gas-filled spaces and resorption of bubbles back into body fluids. This process presumably results in a diminution of tissue distortion, resolution of vascular compromise, and reduced bubble–endothelial surface contact. HBO therapy should be undertaken for at least 4 hours because elimination of bubbles may be reduced in areas of poor flow where sludging and edema exist [1]. It must be remembered that recompression acts only on the primary cause of these syndromes and not necessarily on any of the secondary effects that may result (e.g., endothelial dysfunction, activation of the inflammatory cascade).

Hyperoxygenation results from a markedly enhanced arterial O$_2$ content, primarily from O$_2$ dissolving more readily into the plasma.
Although the oxyhemoglobin dissociation curve remains unchanged, the arterial partial pressure of O\textsubscript{2} may reach 2,000 mm Hg on a fractional inspired oxygen concentration of 100\% and an ambient pressure of 3 ATA \cite{1,19}. In the clinical setting, however, these high plasma O\textsubscript{2} concentrations are never transmitted fully to the tissue level as a result of progressive arteriolar vasoconstriction from the disease process itself, as well as a direct effect from the increasing O\textsubscript{2} concentration. Local tissue perfusion, although reduced further by HBO, is still sufficient to cause supranormal tissue partial pressure of O\textsubscript{2} levels of approximately 500 mm Hg. HBO allows the delivery of nearly 60 mL of oxygen per L of blood (vs. 3 mL per L at atmospheric pressure), a rate sufficient to support resting tissues just on the basis of the O\textsubscript{2} dissolved in solution alone. In practice, the physiologic effects of high concentrations of O\textsubscript{2} to induce generation of O\textsubscript{2} free radicals and pulmonary O\textsubscript{2} toxicity necessitates that periods of hyperoxygenation be alternated with periods of lower fraction of inspired O\textsubscript{2} breathing to avoid potentially severe complications \cite{1,2,17,19}.

Opinions regarding the optimal hyperbaric regimen for AGE and DCS have varied in terms of the simulated depth (i.e., pressure) required, recompression time necessary, and inspired gas concentrations used. Common recompression guidelines in use today include US Navy Treatment Tables 5, 6 and 6A. Tables 6 and 6A are illustrated in Figure 177.2 and Table 177.5 \cite{1,2,17}. Other popular recompression tables in use worldwide include COMEX Table 30 and Royal Navy Tables 71 and 72 \cite{6}.

\textbf{FIGURE 177.2} US Navy Treatment Tables 6 and
Treatment Table 6A is shown in its entirety and is used when symptoms are suspected to be as a result of arterial gas embolism or severe decompression sickness. Treatment Table 6 is superimposed (starting at dotted line) and is seen to begin with a simulated pressure descent on 100% fractional concentration of oxygen to 60 ft. at a rate of 25 ft. per minute. Thereafter, the tables are the same. Treatment Table 6 is recommended for treatment of type II or type I decompression sickness when symptoms are not relieved within 10 minutes at 60 ft. Nonshaded areas are periods of breathing room air. Shaded areas are periods of breathing 100% fractional concentration of oxygen. Individual time periods are shown first, with total elapsed time indicated underneath.

</table>
Hyperbaric treatment recommendations for DCS are loosely based on the general category of illness patterns described previously [1,2,17]. In general, those patients with type I “pain-only” DCS (except for cutis marmorate) are generally in a more stable medical condition on arrival to a recompression facility; therefore, more time is available to perform a thorough and detailed physical examination before chamber treatment. Particular emphasis should be placed on the neurologic examination so that serial examinations can document the presence of any subtle findings that can be used to monitor the response to therapy. If type I DCS subjects have complete relief of symptoms within the first 10 minutes of recompression at a pressure of 2.8 ATA (equivalent to 60 ft seawater), US Navy Treatment Table 5 (basically a shortened version of US Navy Table 6) is appropriate [2].

Subjects with type I DCS with an inadequate response to initial recompression at 2.8 ATA, the presence of cutis marmorate or with any neurologic abnormality, no matter how subtle (i.e., type II DCS or AGE), requires initial treatment according to at least US Navy Treatment Table 6 [2]. This would allow for more optimal therapy of any developing neurologic deficits, and it would, therefore, be expected to decrease the overall occurrence of progression to type II DCS.

Extensive clinical experience has found no objective benefits to starting recompression at levels greater than 2.8 ATA [1,17]. Consensus opinion now recommends that subjects experiencing type II DCS or AGE who have an improvement of symptoms within the first O₂ breathing period (20 minutes) should continue recompression therapy using Treatment Table 6 [2]. If instead, these same subjects have symptoms that are unchanged or worsen within 20 minutes of recompression on air at 2.8 ATA, additional recompression on air to a depth equivalent to cause symptom relief or significant improvement (not to exceed 6 ATA or 165-feet seawater pressure) is performed. These subjects then follow Treatment Table 6A [2]. For patients who do not respond adequately to standard protocols, extension periods or change to other established
protocols might be indicated and are decided on an individual basis [1,2,17].

Prevention

There are a limited number of time-tested recommendations that can be made in an effort to minimize the occurrence of DCS. These would include (a) following prescribed “no-decompression” limit diving profiles that factor in the duration of time spent at specific depths and duration of surface intervals between repetitive dives; (b) limiting ascent rates from depth to speeds slower than the ascent rate of the diver’s exhaled air bubbles; and (c) avoiding any hypobaric insults in the postdive period with no flying for at least 12 hours in all divers, delay in flying for 24 hours or more if a dive profile included any mandatory decompression stops, and finally, flying should be prohibited for at least 72 hours after recompression therapy has been administered for DCS or AGE. As alluded to earlier, hypobaric stresses in these instances may result in new onset of one of these syndromes or for the recurrence of one of these previously treated disorders.

Extensive ongoing research is underway to evaluate the potential preventative roles of predive aerobic exercise [20,21], during-dive exercise [22,23], exogenous nitric oxide [21,24], predive normobaric O₂ [25], and predive hyperbaric O₂ [26,27]. These preconditioning agents are hypothesized to upregulate endogenous antioxidants, moderate inflammatory injury, and/or inhibit reperfusion injury. All studies have noted the existence of substantial variability among individuals in the degree of bubble formation detected and the resultant incidence of DCS.

The higher-than-expected incidence of PFO among divers with severe or unexplained DCS suggests an increased risk for DCS in the presence of a PFO and raises the question that PFO closure procedures may represent another possible avenue of prevention of AGE and DCS. While it has been shown by small studies that PFO closure can decrease or eliminate the arterialization of VGE [28], available data does not confirm that PFO closure procedures reduce the incidence of DCS [13,28,29]. Further, the risk–benefit assessment for surgical or catheter-delivered PFO closure procedures is still debated. The reported risk for serious complications from PFO closure procedures is estimated at 1% or higher, which is an order of magnitude greater than the risk of DCS or AGE for recreational divers. Current consensus is that routine screening for PFO is not warranted for the general diving population. Screening (following a strict protocol) can be considered for certain high-risk subgroups for DCS or AGE (e.g., those with prior DCS or AGE events; family history of PFO or atrial septal defect; divers who perform heavy exertions at deeper depths or repetitive dives). PFO closure can be offered on an individual basis for
those who desire to continue higher risk dive profiles. Avoidance of risk is generally a better option than attempts at risk mitigation or cure after the fact.

Chapter 178

Acute Inhalation Injury

ANNA NOLAN • MICHAEL D. WEIDEN • LAWRENCE C. MOHR, JR • DAVID J. PREZANT

OVERVIEW

Chemicals are a main component of most industrial processes. These industries generate many trillion dollars of economic activity in the United States and Europe and are integral to many local economies. Owing to the close proximity of these industries, communities must be equipped to medically manage acute exposures. If inhaled, many have the potential to cause asphyxiation or life-threatening acute lung injury. Although recent events have increased concern that toxic gases may be used as weapons of mass destruction, accidental exposures remain the greatest health threat [1]. Individuals may be exposed to the accidental release of toxic gases in the workplace [2] or in the general environment, including the home [1].

Smoke inhalation is another major cause of acute inhalation injury [3]. Thousands of individuals are smoke inhalation victims each year, having been exposed to toxic gases and airborne particulate matter from the burning of a variety of materials [4]. Smoke inhalation most commonly occurs as a result of industrial or residential fires, where large amounts of carbon monoxide (CO), hydrogen cyanide (HCN), hydrogen chloride, acrolein, sulfur dioxide, phosgene, and other toxic, irritant gases are produced and released into the environment in various respirable forms (Table 178.1).

Toxic agents can be inhaled in several different forms or physical states. A gas at standard temperature and pressure has the ability for its molecules to diffuse freely and be distributed uniformly throughout any container. The density of a gas is expressed relative to air. The denser the gas, the heavier it is. Gases that are denser than air will typically gravitate to low areas. Cold gases are denser than the same gas at higher temperatures. A vapor is a substance in the gaseous state that normally exists as a liquid or solid and is formed when a substance is heated above its critical temperature, which is the temperature at which it cannot be liquefied regardless of the amount of pressure. A fog is a liquid aerosol formed by condensation of a substance from a gaseous to a liquid state. Dusts are fine particles of a solid organic or an inorganic material that are small enough to be airborne, typically ranging from 0.1 to 25.0 μm in diameter. Fumes are extremely fine solid particles that are dispersed into the air by the combustion or melting of solid materials, particularly metals. Fumes usually consist of particles that range from 0.001 to 1.0 μm in diameter. Smoke consists of airborne particles resulting from the incomplete combustion of organic materials. These particles either contain or are coated with multiple chemical substances resulting from combustion and range in size from less than 0.3 μm to greater than 10 μm in diameter.

The nature of the acute injury will depend on the chemical and physical properties of the inhaled toxicant, the pathophysiologic mechanism by which the toxicant causes injury, the dose received, and whether prior pulmonary disease exists. This chapter focuses on the diagnosis and treatment of acute inhalation injury resulting from asphyxiant gases, toxic irritant gases, and smoke.
ASPHYXIANT GASES

Background

Asphyxiants cause tissue hypoxia. They are classified as either simple or chemical asphyxiants based on their mechanism of toxicity. Simple asphyxiants displace or dilute oxygen in the ambient atmospheric air, causing a decrease in the fraction of oxygen in inspired air (FiO₂). Chemical asphyxiants, on the other hand, interfere with physiologic processes associated with the uptake, transport, or utilization of oxygen. Simple asphyxiants include common gases such as carbon dioxide, natural gas, propane, methane, nitrogen, and acetylene. They may be lighter or heavier than air (Table 178.2). Simple asphyxiants that are lighter than air accumulate and displace oxygen in higher areas first, whereas those that are heavier than air accumulate and displace oxygen in low-lying areas first. Chemical asphyxiants can be further characterized as those that decrease oxygen-carrying capacity, such as carbon monoxide, and those that inhibit oxygen utilization by cells, such as HCN (Table 178.3). Medical problems related to the inhalation of the most common asphyxiants are discussed in the subsequent sections.

Carbon Dioxide

Pathophysiology

Carbon dioxide (CO$_2$) is the most common simple asphyxiant. It is produced by aerobic metabolism and is exhaled into the atmosphere by humans and other animals. It is also a by-product of carbohydrate fermentation, the combustion of carbonaceous material, and the oxidation of coal contaminants. It has many uses such as for cooling, fire extinguishing, hydrofracking, and when used for cooling in the solid form is known as dry ice [5]. CO$_2$ is heavier than air and reduces FiO$_2$ simply by diluting and displacing oxygen in ambient air. The National Institute of Occupational Safety and Health occupational standards for CO$_2$ are 5,000 ppm for an 8-hour time weighted average, and 30,000 ppm for a 15 minute short-term exposure limit [5]. However, studies investigating the effect of CO$_2$ at lower concentrations show that even at 1,000 ppm, a level often exceeded in classrooms in California and Texas, cognition and mentation can be significantly affected [6]. Most deaths from CO$_2$ asphyxiation result from the confinement of an individual in a poorly ventilated space. Such closed-space confinement prevents air with a normal FiO$_2$ from entering while exhaled CO$_2$ is accumulating and displacing oxygen inside. Simple asphyxiation from CO$_2$ has also been reported from environmental exposures. In 1986, for example, simple asphyxiation caused approximately 1,700 deaths from a cloudy mist of CO$_2$ and water droplets that rose suddenly from a lake in Cameroon [7]. Asphyxiation from CO$_2$ has also been reported by off-gassing from dry ice in a confined space [8,9].

In general, once the ambient CO$_2$ increases to the point where the FiO$_2$ has decreased to 0.15, acute signs and symptoms of hypoxia begin to appear within minutes. These include dyspnea, tachypnea, tachycardia,
confusion, incoordination, and dizziness. As the FiO$_2$ decreases below 0.10, lethargy or coma may develop as a result of cerebral edema, and cardiopulmonary arrest may occur. Brain damage sustained as a result of extensive cerebral edema or prolonged hypoxia may be permanent in individuals with these conditions who are resuscitated and survive. It is unlikely that life can be sustained for more than several minutes with a FiO$_2$ less than 0.06 [10].

**Diagnosis and Management**

CO$_2$ asphyxiation should be considered for any patient who presents with clinical signs of hypoxia, is unconscious, or is found to be in cardiopulmonary arrest after removal from an enclosed space or another source of potential CO$_2$ exposure. Clinical signs are nonspecific and related to the magnitude of hypoxia, as indicated earlier. Arterial blood gases, serum electrolytes, and measurement of the anion gap should be obtained. During and shortly after CO$_2$ asphyxiation, arterial blood gas analysis would be expected to show decreased arterial oxygen tension (PaO$_2$) and elevated carbon dioxide tension (PaCO$_2$). However, both PaO$_2$ and PaCO$_2$ typically return to normal shortly after the patient is removed from the source of CO$_2$ exposure. Once the patient breathes oxygenated air, CO$_2$ is rapidly excreted by hyperventilation. Most patients will be acidotic at the time of presentation as a result of respiratory acidosis from CO$_2$ retention and concurrent lactic acidosis from hypoxia. Lactic acidosis will cause an elevated anion gap. The respiratory acidosis typically resolves shortly after removal from the source of CO$_2$ exposure. The lactic acidosis will resolve once tissue oxygenation returns to normal but usually takes longer to resolve than the respiratory acidosis. The hypoxia caused by CO$_2$ asphyxiation can cause cardiac dysrhythmias and myocardial infarction, especially for individuals with underlying heart disease. Canine models of acute exposure to lethal levels of CO$_2$ show hypoxia, acidosis, and severe hypokalemia [5]. Possible electrocardiographic changes include inverted T-waves, depressed ST segments, and prominent U-waves. Therefore, it is recommended that an electrocardiogram and serial cardiac biomarkers be obtained for all patients.

Removal from the source of exposure and administration of oxygen are the only specific therapies for CO$_2$ asphyxiation. If the patient is alert, has spontaneous respirations, and has a patent airway, it is recommended that high-flow oxygen be administered by a nonrebreather mask.
Endotracheal intubation will be required if adequate oxygenation cannot be achieved by the use of a face mask or the patient has suffered mental status changes or cardiopulmonary arrest. Additional supportive care, such as cardiopulmonary resuscitation, hemodynamic support, and mechanical ventilation should be used as required by the patient’s overall condition. Cardiac dysrhythmias and myocardial infarction should be aggressively treated. Most victims of CO₂ asphyxiation will recover completely if removed from the source of CO₂ exposure prior to cardiopulmonary arrest and given medical treatment as soon as possible. Individuals who have experienced a prolonged period of hypoxia, however, may have irreversible brain damage and chronic neurologic sequelae even after they are successfully resuscitated.

## Carbon Monoxide

### Pathophysiology

Carbon monoxide (CO) is a colorless, odorless, tasteless, nonirritating gas. It is the most common chemical asphyxiant and the second most common atmospheric pollutant after CO₂. CO is produced in a variety of ways, including incomplete combustion from fires, faulty heating systems, internal combustion engines (including gas-powered generators placed in poorly ventilated areas during electrical failures), wood stoves, charcoal grills, volcanic eruptions, and a variety of industrial processes. Hepatic production of CO occurs with poisoning from methylene chloride that is commonly found in paint thinners and is easily absorbed through the skin.

More than 5,000 deaths are attributed to CO poisoning in the United States each year [11]. Most are intentional from exposures to motor vehicle exhaust. The minority are accidental and caused by fires or the use of poorly ventilated generators following storms, blackouts, or other disasters [12,13]. CO poisoning is responsible for 80% of fatalities related to smoke inhalation [14]. Twenty-five percent of fatalities from CO poisoning occur in persons with underlying cardiopulmonary disease [15].

CO easily diffuses across alveolar-capillary membranes in the lung and is rapidly taken up by erythrocytes in the pulmonary capillary blood. It binds to the iron moiety of hemoglobin with an affinity that is approximately 240 times greater than the affinity of hemoglobin for oxygen. Thus, CO competes with oxygen for hemoglobin binding sites and, as a result of its greater affinity, displaces oxygen from hemoglobin. The binding of CO to the iron moiety also creates an allosteric change in the hemoglobin molecule that inhibits the off-loading of oxygen in the
peripheral tissues and causes a shift of the oxyhemoglobin dissociation curve to the left. CO also interferes with intracellular oxygen utilization by inactivating intracellular respiratory enzymes, such as cytochrome oxidase [16]. Thus, the cumulative effect on peripheral oxygen delivery and utilization is greater than that expected from decreased oxygen transport alone. Reoxygenation injury of the brain has also been described [17]. One mechanism for reoxygenation injury appears to be lipid peroxidation of the brain by xanthine oxidase that is generated by peroxidases and reactive oxygen species produced by activated neutrophils that become sequestered in the microvasculature of the brain following, but not during, CO poisoning [18]. In summary, CO toxicity involves four pathophysiologic mechanisms: (a) a decrease in the oxygen-carrying capacity of blood; (b) decreased oxygen delivery to peripheral tissues as a result of the left shift in the oxyhemoglobin dissociation curve; (c) mitochondrial dysfunction and impairment of cellular respiration by inhibition of cytochrome oxidase activity; and (d) lipid peroxidation of the brain during reoxygenation. Lipid peroxidation leads to reversible demyelination in areas of the central nervous system, including corpus callosum, the internal/external capsule, optic tracts, and periventricular parenchyma [12].

The presentation of individuals with CO poisoning is highly variable with nonspecific symptoms and signs that are loosely correlated to carboxyhemoglobin levels (Table 178.4). Early symptoms of CO poisoning include headache, dizziness, sore throat, nausea, shortness of breath, and fatigue. These symptoms can mimic those of a nonspecific viral syndrome, especially when an entire family is affected from CO exposure related to a faulty home heating system during the winter months. Impaired ability to concentrate occurs in more than half of affected individuals, and 6% have been reported to experience loss of consciousness. The severity of symptoms appears to correlate better with duration of exposure than with carboxyhemoglobin levels [19]. The brain and heart are very sensitive to CO intoxication, and both neurologic and cardiovascular impairment predominate with prolonged exposures. Mental status changes, and seizures, sudden loss of consciousness, tachypnea, tachycardia, cardiac dysrhythmias, hypotension, and myocardial ischemia are likely to occur when the carboxyhemoglobin concentration exceeds 20%. Cardiovascular disorders may occur at lower concentrations among subjects with preexisting cardiopulmonary diseases. Evidence of myocardial ischemia has been observed in one-third of individuals with moderate to severe CO intoxication, and it has
recently been reported that myocardial injury, as determined by elevation of serial cardiac biomarkers, is an independent predictor of mortality from CO poisoning [15,20,21]. Metabolic acidosis, owing to increased lactate production from anaerobic metabolism, is a common consequence of tissue hypoxia. Rhabdomyolysis can occur as a consequence of impaired aerobic metabolism in skeletal muscle cells. Renal failure can develop as a consequence of rhabdomyolysis, but this occurs infrequently [22]. Carbon monoxide poisoning is almost always fatal when the carboxyhemoglobin concentration exceeds 60% [14,23].

Fetal hemoglobin has a much greater affinity for CO than adult hemoglobin. Therefore, during pregnancy, the fetus may be more susceptible to CO poisoning than the mother. Once the mother is removed from the source of CO, clearance of carboxyhemoglobin may take four to five times longer in the fetus than it did in the mother [24]. Thus, the effective duration of CO exposure is considerably longer for the fetus than it is for the mother. It has been reported that severe CO toxicity in pregnant women can produce ischemic brain damage to the fetus and
increase the risk of stillbirth [25,26].

CO poisoning can result in a delayed neuropsychiatric syndrome that may present at any time between 3 days and 4 months after apparent recovery from acute effects [14,27]. The syndrome has been reported to occur in 10% to 30% of individuals who survive CO poisoning. Symptoms include cognitive impairment, personality changes, Parkinsonism, incontinence, focal neurologic deficits, dementia, and psychosis. There is poor correlation between the development of the delayed neuropsychiatric syndrome and carboxyhemoglobin levels. Loss of consciousness during the acute illness phase, carboxyhemoglobin 25% or more, duration of exposure, and age appear to be significant risk factors [19]. Brain imaging studies have shown that the areas most affected are the globus pallidus and deep white matter [14]. The exact mechanism for the development of this syndrome is unclear, but it is thought to be associated with reoxygenation brain injury, as discussed earlier. Most affected individuals recover within 1 year, although some may have chronic, long-term neurologic or psychiatric impairment [14]. A more comprehensive discussion of the neurologic aspects of carbon monoxide poisoning is presented in chapter (Chapter 156).

**Diagnosis and Management**

Because CO poisoning can present with a variety of nonspecific signs and symptoms, a high index of suspicion is needed to make the diagnosis. History of potential exposure to a source of CO and elevation of arterial or venous blood carboxyhemoglobin level can point to the diagnosis [12]. Cherry-red lips, cyanosis, and retinal hemorrhages have been reported in some cases of high-dose CO poisoning, but these signs occur infrequently, and diagnosis depends on clinical history substantiated by increased levels of carboxyhemoglobin in arterial or venous blood [14]. Carboxyhemoglobin is most accurately measured by CO-oximetry because routine pulse oximetry cannot distinguish between carboxyhemoglobin and oxyhemoglobin, which both read at 660 nm [28]. PaO₂ is also of little value, because in the absence of coexistent lung injury, it is normal. This is owing to the fact that a CO partial pressure of only 1 mm Hg in arterial blood can saturate more than 50% of hemoglobin without affecting gas exchange or the amount of dissolved oxygen. Exposure to CO generally causes elevation of carboxyhemoglobin to greater than 3% to 4% in nonsmokers and higher than 10% in smokers [28]. Recently, noninvasive CO-oximetry has become commercially available. Studies show that it has a high degree of specificity but poor sensitivity [29,30]. Using a cutoff of 15% carboxyhemoglobin, noninvasive CO-oximetry had a poor sensitivity of 48% (correctly identified only 11 of 23 patients with elevated levels) but an excellent
specifity of 99% (correctly identify 96 of 97 patients with levels below 15%) [30]. Until further studies are done, this would suggest that its primary value is for ruling out the diagnosis when there are no symptoms. It is probably most useful in environments where it is difficult or not possible to obtain blood measurement such as by emergency medical service (EMS) units in the prehospital environment, but should be used cautiously [31].

Patients with CO poisoning resulting from smoke inhalation should also be examined for evidence of thermal injury to the skin or airways. If CO poisoning is the result of a suicide attempt, a drug screen and serum ethanol, salicylate, and acetaminophen levels should be obtained. Another advantage of measuring the arterial carboxyhemoglobin level is that it also allows for simultaneous measurement of arterial pH. The pH can be used in conjunction with the anion gap and the serum lactate level to assess the degree of metabolic acidosis which when elevated is an independent predictor of poor prognosis [14]. PaCO₂ is only helpful in assessing the ventilatory response to hypoxia and ventilatory compensation for lactic acidosis and should be obtained when mental status is abnormal or there is a prior history of chronic pulmonary disease. The serum creatine kinase level will be elevated if rhabdomyolysis has occurred. An electrocardiogram and serial cardiac biomarkers should be obtained in all patients to evaluate the possibility of myocardial ischemia or infarction. Single-photon emission computed tomography (CT) perfusion scintigraphy (Table 178.5) has been cited as a technique of choice to diagnose cardiac involvement after CO exposure [32]. Because CO lowers the threshold for the development of ventricular dysrhythmias, patients should be carefully monitored until they are discharged from the emergency department or hospital [33]. The chest radiograph is usually normal, but signs of noncardiogenic pulmonary edema can rarely be seen in cases of severe CO poisoning [23], especially if there is coexistent smoke inhalation. CT of the head is useful if there is a need to rule out other causes of neurologic impairment in this acute setting.

Significant morbidity and mortality with accidental chlorine exposure following train derailment 2007 Prospective study 605 Majority developed symptoms and needed medical care, 25 developed pulmonary edema, 9 deaths from asphyxia and pulmonary edema and its complications. [79]

Lung function in fire Department Rescue Workers followed for 7 years after exposure to World Trade Center Dust. 2010 Prospective Study 12,781 Exposure to World Trade Center dust led to large declines in FEV<sub>1</sub> during the first year. Overall, these declines were persistent, without recovery over the next 6 y, leaving a substantial proportion with abnormal lung function. [132]

SPECT, single-photon emission computed tomography; ECG, electrocardiogram; ARDS, acute respiratory distress syndrome; FEV<sub>1</sub>, forced expiratory volume in 1 second.

The initial treatment of CO poisoning is prompt removal from the source of exposure and administration of 100% oxygen via a nonrebreather mask to reduce the half-life of carboxyhemoglobin from 4 to 6 hours and 40 to 80 minutes [14,34]. Patients who are unconscious or have cardiopulmonary compromise should be intubated and receive 100% oxygen by mechanical ventilation and hyperbaric oxygen therapy (HBOT) may be considered (see later). Oxygen should be administered until the carboxyhemoglobin level returns to normal. Pregnant women typically require oxygen for a longer period of time, because it takes
longer for CO to be excreted from the fetus as a result of the greater affinity of fetal hemoglobin for CO [24].

Most patients with mild to moderate CO poisoning can be treated in the emergency department and discharged after the carboxyhemoglobin level has returned to normal and all abnormal signs and symptoms have resolved. Patients with severe CO poisoning, coexistent smoke inhalation, serious underlying diseases, neurologic or cardiopulmonary instability, or whose poisoning was an intentional suicide attempt should be admitted to the hospital for treatment and close observation.

HBOT has been used to treat patients with either extreme levels of CO poisoning (≥25% carboxyhemoglobin) or end-organ sensitivity to CO at elevated but lower levels. Examples of this might include neurologic abnormalities or hemodynamic instability that are felt to be caused by CO poisoning. Although as many as 18 possible different HBOT protocols exist, there is no general consensus and it is considered the mainstay of treatment for severe CO poisoning [35]. HBOT is performed by placing the patient in a chamber that is highly pressurized with 100% oxygen. HBOT produces a large increase in the amount of dissolved oxygen in blood that in turn greatly increases the partial pressure of oxygen in the blood. The half-life of carboxyhemoglobin decreases as the partial pressure of oxygen in the blood increases. HBOT with 100% oxygen at a pressure of 2.5 to 3.0 atmosphere will reduce the half-life of carboxyhemoglobin from 4 to 6 hours to approximately 20 minutes [14,23,36].

Several animal studies suggest that HBOT may attenuate the development of delayed neuropsychiatric symptoms following CO exposure [37]. Although the efficacy of HBOT for preventing the development of the delayed neuropsychiatric syndrome in humans following CO poisoning has not been conclusively established [38], many experts argue for its use when the levels exceed 20% to 25% [38,39]. HBOT will, however, hasten the resolution of symptoms and when available is currently recommended for patients with CO poisoning meeting any of the following criteria: any period of unconsciousness, coma, or persistent neurologic abnormalities; carboxyhemoglobin level of 25% or more; metabolic lactic acidosis; or cardiac dysrhythmias [14,15,19,27,40–42]. If myocardial ischemia is present, most experts believe cardiac catheterization with stenting of the blocked vessel to be the urgently required procedure. In a pregnant patient, fetal distress even at lower percentage of carboxyhemoglobin elevations would prompt consideration for HBOT if available.
The clearance of CO can also be accelerated by use of normocapnic, hyperoxic, and hyperpnea. In this technique, the patient breathes a hyperoxic gas mixture that contains an FiO$_2$ of 95.2% to 95.5% and a small amount of CO$_2$, in the range of 4.5% to 4.8%, through a nonrebreathing circuit. The resulting increase in minute ventilation increases the partial pressure gradient for oxygen and CO between pulmonary capillary blood and alveolar gas but does not increase the partial pressure gradient for CO$_2$. In a clinical study, normocapnic hyperoxic hyperpnea reduced the half-life of carboxyhemoglobin to 31 minutes compared with 78 minutes for individuals treated with 100% oxygen at normal minute ventilation [43]. CO-poisoned patients in hospitals without access to hyperbaric chambers might benefit from this technique.

The potential benefit of HBOT must be weighed against its inherent risks. HBOT can cause barotrauma, tympanic membrane rupture, increased anxiety, pulmonary edema, hemorrhage, tension pneumothorax, decompression sickness, nitrogen emboli, seizures, and brain damage because of superoxide production [12]. Moreover, there is insufficient evidence that HBOT reduces neurologic damage from CO intoxication. In addition to controversy concerning which patients with CO intoxication might benefit most from HBOT, there is controversy surrounding the need to treat for HCN toxicity (see later) for patients suffering severe CO poisoning from smoke inhalation. The likelihood for cyanide toxicity in smoke inhalation victims increases with increasing carboxyhemoglobin levels and increasing acidosis [44].

Hydrogen Cyanide

Pathophysiology

HCN is a chemical asphyxiant produced by the combustion of nitrogen-containing polymers during fires [44–46]. It is also part of jewelry making and various manufacturing processes (metal plating) and in the reclamation of silver from photographic and radiographic film. It has the potential to be used as a chemical agent during terrorist attacks [47]. It is a colorless, volatile liquid at room temperature, but readily vaporizes into a gas. The gaseous form of HCN easily diffuses across the alveolar membrane after inhalation. Inhaled HCN is lethal in high doses, and its inhalation during a fire may contribute to the mortality of smoke inhalation victims [44–46]. The inhalation of lethal doses of HCN may also occur following accidental releases at industrial facilities or from its use in a terrorist attack.

After inhalation, HCN is rapidly distributed to tissues throughout the
body. At the cellular level, HCN molecules bind to iron-containing sites on cytochrome $a_3$ in mitochondria that inhibits the enzyme's activity toxicity and decreases the cellular utilization of oxygen [44,48].

Cytochrome $a_3$ is a key enzyme in the cytochrome oxidase system that is important for carrying out and sustaining aerobic metabolism within cells. Inhibition of cytochrome $a_3$ by HCN blocks cellular respiration and oxidative phosphorylation, forcing affected cells into anaerobic metabolism.

The binding of HCN to cytochrome $a_3$, and the resulting inhibition of cellular respiration, occurs very rapidly after HCN inhalation, with clinical signs and symptoms occurring within 15 seconds. The clinical effects of HCN intoxication are directly related to its ability to stop cellular respiration. They are nonspecific and identical to the signs and symptoms typically seen during hypoxia. Hyperpnea, dyspnea, tachycardia, agitation, anxiety, dizziness, headache, confusion, nausea, muscle weakness, and trembling are common. Lactic acidosis occurs as a result of anaerobic metabolism and may be severe. Hypotension, flushing, seizures, and Parkinson-like symptoms may occur among cases of severe intoxication. Coma, apnea, and cardiac dysrrhythmias are poor prognostic signs unless prompt treatment is given [49,50].

**Diagnosis and Management**

The diagnosis of HCN poisoning requires a high index of suspicion. It should be suspected in every individual with any of the above signs or symptoms for which there is no other obvious cause and a pertinent history such as smoke inhalation victims, victims of industrial accidents in which cyanide could have been released, and victims of terrorist attacks. Blood and urine cyanide concentrations can be obtained, but because these tests are not routinely performed in most laboratories, results take days to return and, therefore, are only be used to confirm the diagnosis. Treatment for this potentially life-threatening poisoning must be initiated immediately based on diagnostic suspicion alone.

There are several important clues that can be helpful for making a clinical diagnosis of HCN intoxication. In smoke inhalation victims, HCN toxicity should be suspected whenever CO intoxication occurs, and in fact, the likelihood increases with increasing carboxyhemoglobin levels [44]. Regardless of the etiology of HCN exposure, metabolic acidosis with an increased anion gap and an elevated serum lactate concentration should typically be present. Arterial and venous blood gases can provide potentially useful information, with a high index of suspicion when the arteriovenous $O_2$ difference is far less than normal. Because of poor cellular extraction and utilization of oxygen, the arterial oxygen tension is
usually above 90 mm Hg, whereas venous oxygen tension may be significantly elevated above the normal range of 35 to 45 mm Hg. Similarly, arterial oxygen saturation is typically in the normal range of 95% to 100%, whereas the oxygen saturation of mixed venous blood may be in the vicinity of 85% or greater, significantly higher than the normal range of 60% to 80%. This so-called arteriolarization of venous blood can be a useful clue in considering the diagnosis of HCN intoxication [51].

Because HCN poisoning can rapidly progress, treatment must begin as soon as possible in patient presenting with seizures, coma, hypotension, or cardiac arrest in whom HCN toxicity is suspected [52,53]. The US Food and Drug Administration approved two forms of therapy for cyanide toxicity. The Cyanokit antidote consisting of hydroxocobalamin—a precursor to vitamin B$_{12}$. It is a relatively benign substance (see below for adverse reactions) with rapid onset of action. For these reasons, it may be a superior antidote to the older more commonly available cyanide antidote kit (CAK) consisting of sodium nitrite and sodium thiosulfate [54,55]. Hydroxocobalamin has no adverse effect on the oxygen-carrying capacity of the red blood cells and no negative impact on the patient’s blood pressure—significant benefits when treating victims of smoke inhalation. The mechanism of action is surprisingly simple: hydroxocobalamin binds to cyanide forming vitamin B$_{12}$ (cyanocobalamin), a nontoxic compound excreted in the urine.

Victims presenting with seizures, hypotension, or a coma in a setting consistent with cyanide toxicity should be considered candidates for empiric administration of hydroxocobalamin 5 g intravenously over 15 minutes through two intravenous or intraosseous lines. Consideration should be given to obtaining a blood sample for subsequent analysis for HCN and for baseline laboratory tests that could be interfered with by the presence of hydroxocobalamin.

The most common adverse reactions (>5%) include transient chromaturia, erythema, rash (predominantly aciform), hypertension, nausea, headache, decreased lymphocyte percentage, and injection site reactions. Less common allergic reactions include anaphylaxis, chest tightness, angioneurotic edema, and dyspnea. Because of its deep red color, hydroxocobalamin may cause hemodialysis machines to shut down because of an erroneous detection of a “blood leak.” Reddish color of the blood and urine may interfere with some colorimetric laboratory tests (i.e., blood glucose, iron levels, creatinine, total hemoglobin concentration, carboxyhemoglobin, oxyhemoglobin, and methemoglobin)
Sodium nitrite and sodium thiosulfate can also be used for the treatment of HCN poisoning. These antidotes are found in the CAK, along with ampules of amyl nitrite inhalant. Sodium nitrite generates methemoglobin by changing the normal ferrous state of iron in the heme molecule of hemoglobin (Fe\(^{2+}\)) to the ferric state (Fe\(^{3+}\)). The ferric heme molecules in methemoglobin have a high affinity for HCN. Thus, HCN molecules preferentially bind to the methemoglobin generated by sodium nitrate, which in turn prevents HCN from entering cells and inhibiting cellular respiration. The adult dose of sodium nitrite is 300 mg in 10 mL of diluent (30 mg per mL) administered intravenously over 2 to 4 minutes, and the pediatric dose is 0.33 mL per kg of a 3% solution, intravenously over 2 to 4 minutes, not to exceed 10 mL [49,58]. Following the administration of sodium nitrite, sodium thiosulfate should be administered intravenously. Sodium thiosulfate acts as a substrate for rhodanese, a detoxifying enzyme found in the liver. In the presence of sodium thiosulfate, rhodanese catalyses the conversion of HCN cyanide to thiocyanate that is then excreted in the urine. The adult dose is 12.5 g of sodium thiosulfate in 50 mL of diluent (25% solution), administered intravenously at a rate of 3 to 5 mL per minute. The pediatric dose of sodium thiosulfate is 412.5 mg per kg (1.65 mL per kg) of a 25% solution, given intravenously at a rate of 3 to 5 mL per minute [51,58].

The inhalation of amyl nitrite from ampules can be used as a temporizing measure until venous access for the administration of sodium nitrite and sodium thiosulfate is obtained. The inhalation of amyl nitrite should never be considered a substitute for the administration of intravenous sodium nitrite and sodium thiosulfate. In fact, amyl nitrite can itself be associated with serious reactions such as hypotension, syncope, methemoglobinemia, and hemolysis in G6PD-deficient patients. These effects are more pronounced in children, the elderly, and in patients with cardiopulmonary diseases. Dose regimen is difficult to control and could even result in exposure of the health care provider to amyl nitrite’s adverse effects. For these reasons, administration of amyl nitrite may be unwarranted, especially because hydroxocobalamin is now available [59].

One hundred percent oxygen should be administered to all patients with HCN poisoning to maximize the oxygen-carrying capacity of blood. Ventilatory support should be provided as needed. The administration of sodium bicarbonate should be considered for the treatment of severe lactic acidosis in patients who are unconscious or hemodynamically unstable. Arterial blood gas analysis should be used to guide the need for repeat doses of sodium bicarbonate to ensure that metabolic alkalosis does not develop.
Hydrogen Sulfide

Pathophysiology

Hydrogen sulfide (H₂S) is a colorless, highly flammable gas that has the characteristic odor of “rotten eggs.” It is produced in a variety of settings, most commonly sewer systems, manure pits on farms, oil fields, and petroleum refining plants [60–62]. It’s noxious, “rotten eggs” odor is detectable by smell at low concentrations but may not be detectable at high concentrations or after prolonged exposure because of olfactory fatigue. Inhaled H₂S is both a chemical asphyxiant and a respiratory tract irritant. As such, it can produce a variety of clinical effects, including central nervous system dysfunction [63], cardiac dysrhythmias, and pulmonary edema as a result of acute lung injury. The severity of symptoms and prognosis are dependent on the dose of H₂S inhaled.

H₂S blocks the cellular utilization of oxygen by inhibiting the activity of cytochrome a₃, a mitochondrial enzyme of the cytochrome oxidase system that is involved in aerobic metabolism. The pathophysiologic mechanism of H₂S asphyxiation is identical to that of HCN. As with HCN intoxication, disruption of aerobic metabolism leads to arteriolarization of venous blood and causes a shift to anaerobic metabolism within affected cells that, in turn, leads to metabolic acidosis and an elevated anion gap because of increased lactate production. H₂S is lipid soluble and readily crosses the alveolar membrane after inhalation. Inhalation is the primary route of H₂S toxicity. After absorption through the lungs, H₂S easily dissolves in the blood and is rapidly distributed to tissues throughout the body. The respiratory system and organs with high oxygen demand, such as the brain and heart, are particularly vulnerable.

The severity of clinical signs and symptoms associated with H₂S toxicity depends on the exposure dose. Signs and symptoms of asphyxiation and mucosal irritation typically exist simultaneously. Local irritant effects dominate at low exposure doses, whereas pulmonary edema and life-threatening chemical asphyxiation dominate at higher exposure doses. Clinically detectable eye, mucous membrane, and respiratory tract irritation begin to occur at low exposure doses in the vicinity of 50 parts per million (ppm). Low-dose exposures in the range of 50 to 200 ppm are typically characterized by burning of the eyes, increased lacrimation, sore throat, nausea, cough, and occasional wheezing. Because olfactory function is lost at around 100 to 200 ppm, if exposed individuals can still smell the “rotten eggs” odor of H₂S, the
concentration is usually not high enough to cause severe asphyxiation or irritant injury. At exposure concentrations of 200 to 250 ppm, \( \text{H}_2\text{S} \) produces intense irritation of mucous membranes, corneal ulceration, blepharospasm, and dyspnea. Pulmonary edema may occur at these concentrations as a result of irritant-induced acute lung injury [64]. At concentrations greater than 500 ppm, chemical asphyxiation of the brain may produce headache, seizures, delirium, confusion, and lethargy. The central nervous system effects of \( \text{H}_2\text{S} \) toxicity may be exacerbated by hypoxemia secondary to severe pulmonary edema. In survivors, long-term neurologic sequelae, such as ataxia, intention tremor, sensorineural hearing loss, muscle spasticity, and memory impairment, have been reported [61].

Concentrations in the range of 750 to 1,000 ppm will cause severe inhibition of aerobic metabolism within the central nervous system and heart. Myocardial ischemia, arrhythmias, and dilated cardiomyopathy have all been reported after significant exposures [65,66]. As doses increase, loss of consciousness, cessation of brainstem function, and cardiopulmonary arrest will occur.

**Diagnosis and Management**

A high index of suspicion is the key to making the diagnosis of \( \text{H}_2\text{S} \) intoxication. Although blood levels of thiosulfate are helpful in confirming the diagnosis of \( \text{H}_2\text{S} \) poisoning [67], these tests are not readily available in most clinical laboratories. When available, atmospheric measures of \( \text{H}_2\text{S} \) concentration can be used to increase diagnostic suspicion and in classifying the expected the severity of exposure and intoxication. In the absence of specific exposure information, signs of ocular irritation, inflammation of mucosal membranes, and the smell of “rotten eggs” on the clothing or breath of a patient should suggest the diagnosis of \( \text{H}_2\text{S} \) intoxication.

The inhibition of cytochrome \( a_3 \) by \( \text{H}_2\text{S} \) toxicity causes a decrease in the extraction and utilization of oxygen by affected cells. As a result, blood gas analyses typically show a \( \text{PaO}_2 \) in the normal range and an elevated mixed venous oxygen tension (\( \text{PvO}_2 \)), typically in the range of 35 to 45 mm Hg. There may also be a “saturation gap” between the saturation of oxygen (\( \text{SaO}_2 \) or \( \text{SvO}_2 \)) calculated from blood gas data and
the SaO$_2$ measured by CO-oximetry as a result of sulfide ions binding to some oxygen binding sites on hemoglobin molecules, forming molecules of sulfhemoglobin. In addition, both methemoglobin and sulfhemoglobin are produced during the treatment of H$_2$S poisoning with sodium nitrite and amyl nitrite, as discussed later. Therefore, if H$_2$S poisoning is known or suspected, SaO$_2$ should be measured by CO-oximetry. A rapid decline in either PaO$_2$ or SaO$_2$ could indicate the development or progression of pulmonary edema. Serum lactate concentration is typically elevated as a result of the inhibition of aerobic metabolism. The elevated lactate concentration causes a metabolic acidosis and elevation of the anion gap.

The treatment for H$_2$S intoxication is similar to that for HCN intoxication—100% oxygen, antidote, and, possibly, HBOT. One hundred percent oxygen should be given to all patients. Assisted ventilation should be provided as necessary. Sodium nitrite can be used as an antidote to generate methemoglobin by changing the normal ferrous state of iron in the heme molecule of hemoglobin (Fe$^{+2}$) to the ferric state (Fe$^{+3}$). The ferric heme molecules in methemoglobin have a high affinity for H$_2$S [68]. The preferential binding of H$_2$S molecules to methemoglobin results in the formation of sulfhemoglobin that prevents circulating H$_2$S from entering cells and inhibiting cellular respiration. Sodium nitrite should be administered as soon as possible after exposure. Inhalation of amyl nitrite from ampules contained in CAKs can be administered as a temporizing measure until venous access is obtained for the administration of sodium nitrite. The detoxifying enzyme rhodanese is not involved in H$_2$S metabolism, because it is in HCN metabolism. Therefore, sodium thiosulfate or hydroxocobalamin should not be given for the treatment of H$_2$S intoxication. Several case reports argue for a beneficial effect of HBOT in H$_2$S intoxication [69,70]. Basic supportive measures should not be forgotten and include irrigation of the eyes with sterile saline and the treatment of irritant-induced bronchospasm with inhaled $\beta_2$-agonists. Consideration should be given to the administration of sodium bicarbonate for the treatment of severe metabolic acidosis in unconscious or hemodynamically unstable patients. A benzodiazepine, such as diazepam, or a barbiturate can be used to control seizures if present. If a benzodiazepine or barbiturate is given, patients should be carefully monitored for signs of respiratory insufficiency.
IRRITANT GASES

Irritant gases are those that cause chemical injury to the airways and lung tissue upon inhalation. The nature, location, and severity of respiratory tract injuries associated with the inhalation of an irritant gas depend on the physical and chemical properties of the gas, exposure dose, and host factors of exposed individuals. The most important physical and chemical properties are the water solubility and density of the gas. Exposure dose is determined by the concentration of the gas in the environment and the duration of exposure. Minute ventilation, age, and the presence of preexisting respiratory disease are the most important host factors (Table 178.6).

The sites of injury following inhalation of an irritant gas depend on the water solubility of the gas that determines where most of the gas will be deposited in the respiratory tract (Table 178.7). Highly soluble gases, such as ammonia and sulfur dioxide, generally cause irritant damage to exposed mucous membranes, such as the eyes and upper airway (nose, lips, pharynx, and larynx), while sparing the lower airways. At high concentrations, however, a highly soluble irritant gas can overwhelm the upper respiratory tract, and significant amounts may reach the upper and lower airways, thereby producing both mucous membrane and airway
injury. Irritant gases of intermediate solubility, such as chlorine, may produce significant upper airway injury, especially in the pharynx and larynx, but the mucous membrane irritation is usually not as intense as that caused by highly soluble gases. Because of its intermediate solubility, the irritant effects of chlorine will extend more distally at higher concentrations. Thus, high concentrations of inhaled chlorine can produce both upper and lower airway injuries, as well as pulmonary edema as a result of alveolar damage. The inhalation of low-solubility irritant gases, such as phosgene and oxides of nitrogen, typically produces minimal upper airway irritation but can cause intense lower airways and alveolar damage. As a result of lung tissue injury, the development of noncardiogenic pulmonary edema is more likely following inhalation of a low-solubility irritant gas or at high concentrations of gases with intermediate solubility. Irritant gases that are associated with the development of pulmonary edema are listed in Table 178.8. The inhalation of gases that are lipid soluble, but not water soluble, such as chloroform, ether, or other halogenated hydrocarbons, will produce central nervous system effects and little, if any, respiratory injury. Methylene chloride, found in paint remover and other solvents, is an exception to this rule in that high doses may cause pulmonary edema [71].

Irritant gases cause damage to airways and lung tissues by direct cellular injury, cellular injury secondary to the production of free radicals, and production of an inflammatory response. Direct cellular injury is commonly produced by irritant gases that possess either a highly acidic or a highly alkaline pH. Chlorine and phosgene, for example, produce hydrochloric acid when they come in contact with water in mucous membranes. Ammonia forms a strong alkali, ammonium hydroxide, when it comes in contact with water in mucous membranes and airways. Ammonium hydroxide causes liquefaction damage to cells and tissues on contact, with the severity of damage directly related to the hydroxyl ion concentration. Damage to respiratory tract cells and tissues can also be caused by irritant gases that generate the production of free radicals.
Oxides of nitrogen, for example, cause the production of free radicals that cause cellular damage by lipid peroxidation. Both direct cell damage and cell damage secondary to free-radical formation result in the release of a variety of inflammatory mediators that elicit an inflammatory response, thereby causing further oxidant damage to respiratory tract cells. In the airways, the damage caused by irritant gases is manifested by mucosal edema, mucus production, increased smooth muscle contraction, and airway obstruction. At the alveolar level, damage of type 1 pneumocytes occurs followed by capillary leakage caused by epithelial cell damage, disruption of epithelial cell tight junctions, endothelial damage, and increased vascular permeability.

Specific Irritant Toxic Gases

Ammonia

Ammonia (NH₃) is a colorless, pungent, alkaline gas that is less dense than air and highly soluble in water where it forms ammonium hydroxide (NH₄OH). Most inhalational injuries from NH₃ occur as a result of exposures during fertilizer production, chemical manufacturing, oil refining, or the use of cleaning solutions [72]. NH₃ exposures may also occur during the illicit production of methamphetamine [73]. The strong, pungent smell associated with NH₃ is readily detected at a concentration as low as 50 ppm. Few individuals can tolerate a concentration greater than 100 ppm without experiencing nasal stuffiness and irritating cough. As a highly soluble gas, NH₃ primarily causes irritation to the eyes, mucous membranes of the nasal–oral pharynx, and mucosa of the upper respiratory airways. The reaction of NH₃ with water in the conjunctivae, mucous membranes, and upper airway mucosa results in the formation of NH₄OH that causes liquefaction necrosis and intense pain in the eyes, mouth, nose, and throat. The voice is lost shortly after exposure, and patients typically experience sensations of choking and suffocation. The eyes are erythematous, swollen, and may show signs of corneal opacification or ulceration. Edema, ulceration, necrosis, and sloughing of the mucous membranes are typically seen. Airway obstruction as a result of laryngeal edema, bronchial inflammation, bronchoconstriction, and plugs of sloughed epithelium may cause dyspnea, wheezing, and hypoxemia [74]. Death from laryngospasm can occur within minutes after exposure to high concentrations (≥1,500 ppm). With exposure to high concentrations, alveolar damage and pulmonary edema can occur within 24 hours [74]. Secondary bacterial bronchopneumonia may occur
within days. Long-term sequelae of NH₃ inhalation at moderate to severe concentrations include persistent airway obstruction from reactive airways dysfunction syndrome (RADS), asthma, bronchitis, bronchiectasis, and bronchiolitis obliterans [74,75].

**Chlorine**

Chlorine (Cl₂) is a dense, greenish-yellow gas under ambient conditions. It is highly reactive, has intermediate solubility, and has the characteristic pungent odor of bleach. Industrial uses of Cl₂ include the production of chemicals and bleaches, paper manufacturing, textile processing, and the production of polyvinyl chloride. Most Cl₂ exposures result from accidental releases at industrial sites, from ruptured tanks during its transportation, or at swimming pools [76–78]. The relatively high density of Cl₂ causes it to accumulate in low-lying areas, which should be avoided following its accidental release.

Chlorine is detectable by smell at levels of 1 ppm. On contact with mucous membranes, chlorine reacts with water to produce hydrochloric acid (HCl), hypochlorous acid (HClO), and free oxygen radicals. Individuals exposed to low concentrations of Cl₂ typically experience burning of the eyes and mucous membranes, as well as choking and coughing as a result of inflammation of the nasal–oral pharynx and upper airway. At higher concentrations, laryngeal edema, lower airway inflammation, bronchoconstriction, and pulmonary edema can develop. In 2005, a train derailment in Graniteville, South Carolina (Table 178.5) released about 60 tons of chlorine gas [79]. Although the majority presented with wheezing or rales, 17% and 11%, respectively, developed these symptoms later over the next 24 hours [2]. Of the 9 victims of the acute chlorine poisoning, 8 showed cardiomegaly on autopsy, but it is unclear whether it was from a preexisting condition that contributed to their mortality, versus a result of severe lung injury or hypoxemia and subsequent release of vasoactive mediators [2]. The potentially delayed onset of symptoms from acute inhalation of chlorine suggests that exposed individuals with an initial paucity of significant signs and symptoms may not reflect the true severity of the inhalational injury, and exposed individuals may be sent home from the emergency department prematurely. For example, an exposure concentration of 50 ppm may produce relatively mild signs and symptoms initially but can cause death
from laryngospasm or massive pulmonary edema within 1 to 2 hours after exposure. The onset of pulmonary edema may also be delayed up to 24 hours after exposure. At any time within 2 days after Cl₂ exposure, airway inflammation and mucosal desquamation may cause plugging of medium and small bronchi, leading to airflow obstruction and atelectasis. Individuals with a history of asthma or airway hyperactivity may have, particularly, severe bronchospasm.

Secondary bacterial bronchopneumonia may develop as a consequence of ulceration and desquamation of airway mucosa and/or alveolar damage. Fortunately, most exposed individuals will recover completely if they receive prompt medical treatment and survive the acute effects of Cl₂ exposure. However, chronic pulmonary problems may develop in some individuals, including RADS, asthma, bronchiectasis, and bronchiolitis obliterans [78,80,81].

Phosgene

Phosgene (COCl₂) is a heavy, poorly soluble, colorless gas that has the smell of freshly mown hay. Upon contact with water, it hydrolyzes to form CO₂ and HCl. COCl₂ has been used as a chemical warfare agent and was responsible for most gas fatalities during World War I [47]. It is currently use as a chlorinating agent in a variety of industrial processes, including the production of isocyanates, pesticides, dyes, and pharmaceutical agents. Firefighters, welders, and paint strippers may be exposed to COCl₂ as a result of its release from heated chlorinated hydrocarbons, such as polyvinyl chloride [82]. Phosgene is approximately four times as dense as air and tends to accumulate close to the ground and in low-lying areas. Therefore, individuals should avoid low-lying areas following an accidental release.

As a gas with low solubility, COCl₂ is less irritating to the eyes and mucous membranes than NH₃ or Cl₂ and causes mostly irritant damage in the lower airways and cellular damage at the alveolar level. Immediate symptoms include burning of the eyes, increased lacrimation, sore throat, rhinorrhea, cough, choking, dyspnea, and chest tightness, are often mild and resolve within several minutes after cessation of COCl₂ exposure. With high-concentration exposures, laryngeal edema can occur, with stridor and the potential for sudden death. As a result of its low solubility, the mucous membranes and upper airways are typically spared, and there may be few, if any, additional symptoms for 2 to 24 hours following the acute inhalation of COCl₂. However, inhaled COCl₂ will eventually hydrolyze to form HCl in the lower airways and alveoli, causing oxidative and inflammatory injury. As a result, bronchospasm and pulmonary
edema typically develop between 2 and 6 hours following exposure, but pulmonary edema may be delayed for up to 24 hours. The pulmonary edema can progress to the acute respiratory distress syndrome (ARDS) and respiratory failure. Most victims survive without long-term sequela if they receive prompt medical care. Those with ARDS have the worst prognosis and will require assisted ventilation and circulatory support as needed. Chronic problems may develop in some individuals with RADS, asthma, bronchiectasis, and bronchiolitis obliterans [83].

Nitrogen Oxides

The four stable oxides of nitrogen are nitrous oxide (N₂O), nitric oxide (NO), nitrogen dioxide (NO₂), and nitrogen tetroxide (N₂O₄). Oxides of nitrogen are used in the production of dyes, lacquer, and fertilizer. They are also generated in a variety of processes, including arc welding [82], chemical engraving, explosives, and the storage of fresh silage [84]. All oxides of nitrogen can produce serious acute respiratory tract injury upon inhalation. However, NO₂ is the most common and clinically important toxicant in this group. NO₂ is an irritating, low-solubility, dense orange-brown gas. It forms nitric acid (HNO₃) and nitrous acid (HNO₂) upon contact with water.

NO₂ causes silo filler’s disease, one of the best-characterized syndromes of toxic gas exposure. Silo filler’s disease develops following exposure to NO₂ gas that accumulates just above the silage in recently filled, top-loading silos. During the first 2 weeks in the silo, carbohydrates in the silage ferment and produce organic acids. The organic acids then oxidize nitrates in the silage into NO₂. Within hours after it starts to be produced, NO₂ rapidly accumulates to toxic levels of 200 to 2,000 ppm. High concentrations of NO₂ typically persist for 1 to 2 weeks, then decrease. Entry into a silo without proper respiratory protection, especially within the first 2 weeks of the silo being filled with fresh silage, can cause a rapid loss of consciousness and sudden death. The incidence of this disorder is estimated to be 5 cases per 100,000 silo-associated farm workers per year [84].

The lower airways and lung are the primary sites of injury following acute inhalation of NO₂. The low water solubility of NO₂ results in a paucity of eye, mucous membrane, and upper airway irritant symptoms. The most significant effects occur in the lower airways and lungs as a result of the conversion of NO₂ to HNO₃ upon contact with water in bronchial mucosa and alveoli. The clinical response to inhaled NO₂
occurs in three phases [84,85]. The first phase is the *acute illness phase* that typically occurs within the first hour after exposure. The severity of symptoms in this first phase is dose related. At doses up to 100 ppm, cough, wheezing, dyspnea, and chest pain develop as a result of lower airway irritation and bronchospasm. Hypotension may occur in severe cases. At doses greater than 100 ppm, pulmonary edema may develop within 1 to 2 hours after exposure. The hypoxemia resulting from pulmonary edema is further exacerbated by NO₂-induced methemoglobinemia.

Without further NO₂ exposure, symptoms of the *acute illness phase* usually resolve over a period of 2 to 8 weeks. During this *latent phase*, the patient may have mild cough and wheezing, or may be totally asymptomatic. The patient may then develop a *delayed illness phase* that is characterized by the sudden onset of fever, chills, cough, dyspnea, and generalized lung crackles on exam [84,85]. The *delayed illness phase* is characterized by bronchiolitis obliterans. Lung biopsies show this bronchiolitis to be proximal and without organizing pneumonia [64,84,85]. The bronchioles are packed with inflammatory exudate and fibrin that may obliterate the entire lumen. The bronchiolitis obliterans of the *delayed illness phase* may be extensive and cause severe, life-threatening hypoxemia. Symptom severity in the *acute illness phase* does not always correlate with the severity of bronchiolitis obliterans in the *delayed illness phase*. Therefore, patients with relatively mild symptoms in the days following acute NO₂ exposure may experience severe, life-threatening bronchiolitis obliterans and pulmonary edema in the *delayed illness phase*.

---

**Sulfur Dioxide**

Sulfur dioxide (SO₂) is a colorless, dense, irritating gas that is highly soluble in water. It has a readily identifiable, strong, pungent, odor. SO₂ is a common atmospheric pollutant from the combustion of coal and gasoline. It is used in a variety of industrial process, such as bleaching, refrigeration, and paper manufacturing [64,86]. SO₂ forms sulfuric acid (H₂SO₄) upon contact with water in human tissues. As a highly soluble gas, the predominant effects of SO₂ exposure are irritation of the eyes, nose, mucous membranes, pharynx, and upper respiratory tract. Exposure doses greater than 10 ppm typically cause bronchospasm with symptoms of cough, wheezing, dyspnea, and chest pain. Symptom
severity increases with increasing exposure doses. Individuals with preexisting asthma or chronic obstructive lung disease are more likely to develop severe exacerbations [87]. These include RADS, asthma, bronchiolitis obliterans, and restrictive lung disease. Sulfur dioxide in air pollution was also associated with increased cardiovascular mortality (Table 178.5) [88].

Zinc Chloride

Zinc chloride exposure occurs most commonly with the use of smoke bombs when synthetic smoke is created (police operations, military drills, and firefighter training) [89]. After inhalation, the zinc oxide reacts with hexachloroethane. Zinc chloride is an ultrafine particle that can penetrate into the lower respiratory tract. Exposure to the smoke for as little as 1 to 5 minutes can progress to ARDS and death. Initial symptoms can include dry cough, sore throat, shortness of breath, and chest tightness, and often the onset of severe respiratory distress is delayed [89]. Positive findings on auscultation or chest X-ray may not appear until 48 hours later in at least one case report of zinc chloride inhalation [89]. The inhalation of zinc chloride causes tracheobronchitis and pneumonitis. High-resolution CT (HRCT) taken 1 to 3 days after exposure may show ground-glass opacities bilaterally with consolidation in the posterior region of the lungs [90]. Pulmonary function tests on these patients showed mostly restrictive lung disease, and follow-up HRCTs showed varying degrees of pulmonary fibrosis.

Literature on the treatment of zinc chloride-lung injury is sparse, and supportive care is primarily what is used. There is some evidence that the use of N-acetyl cysteine may facilitate zinc clearance. At least one group reported success with the use of extracorporeal oxygen life support in an exposed patient with ARDS [89]. The use of corticosteroids in these patients with lung injury remains controversial.

Heavy Metals

Two common sources of inhalational exposure to heavy metals occur in the occupational setting: cadmium and mercury. Although the most common environmental source for cadmium is smoking, and thus associated with chronic exposure, exposure can occur in the occupational setting in battery factories, zinc smelters, pigment plants, and welding fumes. Symptoms may manifest up to 2 days after exposure, and include respiratory distress, cough, shivering, and fever [91]. Mortality is frequently because of cadmium’s interference with pulmonary cellular function such as repair of DNA and integrity of membrane structure [92]. This direct toxicity leads to pulmonary edema, chemical pneumonitis,
bronchitis, and emphysema [91,92]. Cadmium exposure also causes renal toxicity. A 15-year follow-up study on residents of the polluted Kakehashi river basin in Japan showed that those with cadmium-induced renal damage had higher risk of mortality [93]. Although cadmium exposure has been shown to be a carcinogen in animal studies, human studies are less conclusive and demonstrate varying levels of association with lung and prostate cancer [93].

Although there is no gold standard for treatment of cadmium toxicity, ethylenediaminetetraacetic acid (EDTA) is the most widely accepted chelator [94]. Concomitant administration of glutathione also shows protection against nephrotoxicity. Dosage of EDTA should not exceed 1 g per h, and no more than 3 g per session.
Smoke is a toxic, mixture of gases, vapors, fumes, liquid droplets, and carbonaceous particles generated by the incomplete combustion or pyrolysis of multiple substances at very high temperatures. Approximately 80% of all fire-associated deaths are attributed to inhalational injury [95]. Smoke inhalation is the most common cause of death among fire victims without surface burns. Inhalation injury exerts a greater influence than burn size or age in determining burn mortality [96]. Patients being treated in burn centers have a mortality rate of 29% in the presence of inhalation injury, in comparison with a mortality rate of 2% in its absence [97].

Combustion occurs when oxygen reacts with molecules under intense heat and they become oxidized to smaller compounds. Pyrolysis occurs as a result of heat alone, does not require oxygen, and consists of the melting or boiling of heated material. The toxic products of incomplete combustion or pyrolysis generated in a given setting are determined by multiple factors, including the type of fuel consumed, temperature, rate of heating, and distance from the source [95]. Black smoke results from particles of carbon or soot generated during the combustion or pyrolysis of carbon-containing materials. Common combustible materials in a fire include wood, paper, plastics, polyurethane, paints, and other polymers present in carpeting and upholstery.

Toxic gases are released during combustion and pyrolysis. These gases include both asphyxiants and irritants. CO and HCN are common asphyxiants found in smoke. Aldehydes, acrolein, NO₂, SO₂, and HCl are common irritants found in smoke. These irritant gases are more likely to be released during pyrolysis than combustion [98]. Particulates present in smoke adsorb these irritant chemicals to their surface, which can concentrate the chemicals and increase irritant damage to the respiratory tract upon inhalation [99].

Victims of smoke inhalation are exposed to multiple irritant gases [95,100], but several are particularly notable. Acrolein is an aldehyde released in fires involving polyethylene, polypropylene, vinyl materials, wood, and other organic fuels. At low concentrations, acrolein is intensely irritating to the upper respiratory tract and can cause significant upper airway edema. At high concentrations (>10 ppm), acrolein inhalation can cause life-threatening pulmonary edema [101]. Isocyanate, a known cause of asthma, is also among the toxic products produced in fires. The inhalation of isocyanate contained in smoke can precipitate severe bronchospasm in individuals with or without a history of airway disease.

Smoke particles cause airway damage as a result of direct injury from
heat and steam, irritation of the airway mucosa by the particles themselves, and from inflammation as a result of the irritant effects of toxic chemicals absorbed to their surface. Heat injury from hot gases and steam is usually limited to the upper respiratory tract because heat rapidly dissipates across the upper airways [101]. Smoke particles greater than 10 μm in diameter also contribute to upper airway injury (rhinosinusitis, pharyngitis, laryngitis, and upper airway edematous obstruction), because they do not penetrate into the lower airways unless present at high concentrations. Subglottic or supraglottic edema following smoke inhalation can lead to significant upper airway obstruction. Upper airway obstruction occurs for up to 30% of burn patients and may occur as early as 4 hours or as late as 24 hours after exposure [102]. The production of upper airway edema is because of a variety of factors, including direct mucosal damage and ulceration from heat and superheated steam, the release of inflammatory mediators from the damaged mucosa, and the production of oxygen free radicals from toxic chemicals on the surface of smoke particles. Acute upper airway edema following smoke inhalation usually resolves within 3 to 4 days. Rarely, thermal injury can produce circumferential, constricting eschars, or scarring of the upper airway after the acute edema resolves. Such eschars can produce chronic upper airway obstruction.

In the large- to medium-sized airways of the chest, tracheobronchitis can develop as a result of smoke inhalation. Severe cough and chest tightness without bronchoconstriction are common presenting symptoms. Tracheobronchitis is as a result of irritant chemical and/or particulate injury. Heat injury is rare and occurs only after the inhalation of superheated steam [101].

Particles less than 3 μm in diameter travel to the distal portions of the respiratory tract and can cause small airways and alveolar injury. Lower airway penetration by small smoke particulates can cause irritation, inflammation, and bronchoconstriction. Individuals with preexisting asthma or chronic obstructive pulmonary disease may experience exacerbations, but bronchoconstriction can also occur in individuals with no prior history of airway disease. Small smoke particles can also cause alveolar-capillary injury in the lung parenchyma by direct oxidative damage from adsorbed irritants and by oxygen free radicals and inflammatory mediators released by neutrophils that migrate to areas of irritant damage. Rarely, pulmonary edema can occur as a consequence of alveolar-capillary injury and may occur hours to days after smoke inhalation. Although pulmonary edema occurs among far less than 10%
of smoke inhalation victims, it has a high mortality rate [103].

Airway injury, whether it is tracheobronchitis or small airway bronchoconstriction, can cause sloughing of necrotic tissue into the lower airways that can lead to mucous plugging, bronchial obstruction, atelectasis, hyperinflation, and altered mucociliary clearance. Secondary bacterial pneumonia can develop in obstructed lung segments or as a result of alveolar damage adversely affecting local immunodefenses.

Most smoke inhalation deaths are caused by asphyxiation as a result of CO or HCN in the inhaled smoke [44–46,104]. CO intoxication is responsible for 80% of smoke inhalation fatalities, and approximately one-fourth of these occur in victims with underlying cardiac or pulmonary disease [14]. NO₂ may also be a component of inhaled smoke. In addition to being a potent irritant, NO₂ can cause the development of methemoglobinemia, which further decreases the already impaired oxygen-carrying capacity resulting from carboxyhemoglobinemia. Coexisting HCN intoxication should be considered in all smoke inhalation victims with CO intoxication, especially those with clinical evidence of altered neurologic or cardiac status. In a study from Paris, a clear association was found between blood HCN levels and percent carboxyhemoglobin levels [44]. This association was strongest in patients with metabolic acidosis and elevated lactate levels [44]. In a study from the Dallas County Fire Department, an HCN blood level above 1.0 mg per L was a strong predictor of death, but the association between CO and HCN levels was not strong [105]. In this study, of the 144 patients who reached the emergency room alive, 12 had blood cyanide concentrations exceeding 1.0 mg per L and 8 of the 12 subsequently died. Among these 12 patients, the relationship between percent carboxyhemoglobin levels and HCN blood levels was poor. For example, the highest percent carboxyhemoglobin level found was 40.0%, in a patient with a blood HCN level of 1.20 mg per L. The highest HCN level found was 11.50 mg per L in a patient with a percent carboxyhemoglobin level of 22.4%.

**Diagnosis and Management of Irritant Toxic Gases, Including Smoke Inhalation**

The most important factors for the diagnosis of toxic inhalational injury are a history of circumstances that caused the exposure, identification of the specific toxic gas to which an individual has been exposed, and an estimate of the exposure concentration. Exposure duration is based not only on exposure time but also on the patient’s minute ventilation during that time. Chemical analyses of material at the site of exposure, if available, can be particularly helpful in identifying the offending toxicant and estimating its exposure concentration. The relative solubility of a
toxic gas can be helpful in determining the areas of the respiratory tract where irritant injuries are most likely to occur, and obviously patients with preexisting pulmonary disease are most at risk. When the irritant toxic gases are in the setting of smoke inhalation, the exposure will be to multiple gases and particulates. Facial burns, singed eyebrows, soot in the upper airway, and carbonaceous sputum make smoke inhalation highly likely.

The management of acute inhalational injury from toxic irritants is at first supportive. All contaminated clothing should be removed to prevent further inhalation and percutaneous absorption of the toxic substance. Superficial burns should be treated conservatively with a topical antibiotic such as silver sulfadiazine. The eyes should be thoroughly flushed with sterile normal saline as soon as possible. Careful attention to the eyes is important because cataracts can occur following heavy exposures. Humidified oxygen should be given by face mask. Not everyone exposed to fire smoke warrants hospital admission. Victims with mild inhalation exposures may be treated and released if they are (i) asymptomatic with normal mental status and absent of confusion; (ii) no burns, carbon material, or edema in the upper airway; (iii) normal pulmonary examination without signs of respiratory distress, stridor, or wheeze; and (iv) if available a pulse oximeter and noninvasive carboxyhemoglobin reading that are normal or at baseline. Upon release, patients should be advised to seek medical attention if symptoms occur or reoccur, because the clinical manifestations of inhalation injury may take 4 to 24 hours to develop [103]. It is for this reason that borderline patients or patients with significant comorbidity should be observed rather than released whenever possible.

The medical evaluation after any exposure to potentially toxic irritant gases should focus on assessing the nature and extent of upper and lower respiratory tract injury, the adequacy of oxygenation, cardiac function, and the hemodynamic stability of the patient. Inhalation victims may be unconscious or have altered mental status at the time of presentation. Typical patient complaints include eye irritation, headaches, confusion, sore throat, cough, chest tightness, and difficulty breathing. Common physical findings include irritation of the eyes, skin and other exposed mucosal surfaces, tachypnea, cough, stridor, wheezing, and rhonchi. Rales on presentation are unusual, because pulmonary edema is a later complication [103].

Arterial blood gases, oxygen saturation, should be obtained on all patients. The methemoglobin level should be measured in patients with suspected NO₂ exposure or after treatment with amyl or sodium nitrites for suspected HCN toxicity. Serum lactate concentration should be measured, and the magnitude of metabolic acidosis should be assessed. Although chest radiographs may be normal shortly after acute exposure,
serial radiographs are useful for detecting the development of pulmonary edema and secondary bacterial pneumonia in hypoxemic individuals. An electrocardiogram should be obtained to detect the presence of myocardial ischemia and cardiac dysrhythmias. Hemodynamic monitoring may be necessary in complex, critically ill patients with pulmonary edema.

The carboxyhemoglobin level, a measure of CO intoxication, should be obtained in all patients with suspected exposure to smoke, fires, or other sources of combustion. If high levels of carboxyhemoglobin, methemoglobin, or HCN exist, the arterial oxygen tension ($\text{PaO}_2$) is not useful in assessing the adequacy of oxygen transport or tissue oxygenation. Arterial oxygen saturation should be measured by CO-oximetry because pulse oximetry and the calculation of $\text{SaO}_2$ from the $\text{PaO}_2$ will overestimate the actual oxygen saturation of hemoglobin.

All individuals with known or suspected inhalational injury should be given 100% humidified oxygen as soon as possible. This will help improve the oxygen-carrying capacity of hemoglobin when high levels of carboxyhemoglobin or methemoglobin are present. High levels of methemoglobin are unusual but, if present, can be treated with intravenous methylene blue. The fraction of inspired oxygen can be titrated down to maintain a $\text{PaO}_2$ greater than 60 mm Hg once carboxyhemoglobin and methemoglobin levels have returned to normal. When available, HBOT should be considered for the treatment of CO intoxication according to the criteria for previously delineated in the section in this chapter. HBOT has been used to treat patients with extreme levels of CO poisoning ($\geq$25% carboxyhemoglobin) or end-organ sensitivity to CO at elevated but lower levels. Examples of this might include neurologic abnormalities or hemodynamic instability that was felt to be caused by CO poisoning.

Severely ill smoke inhalation patients presenting with seizures, coma, hemodynamic instability, and/or severe lactic acidosis should be suspected of having both CO and HCN intoxication [44–46,105]. Blood HCN levels can be measured, but results cannot be obtained in time to make therapeutic decisions, and, therefore, the decision to treat for HCN toxicity should be based on the exposure characteristics and clinical presentation. The NYC Fire Department’s protocol is to intubate such patients; provide hemodynamic support as needed; empirically treat for HCN poisoning with hydroxocobalamin; and, if noninvasive carboxyhemoglobin levels are elevated, to transport to an HBOT center.
In addition, all smoke inhalation victims found in cardiac arrest receive hydroxocobalamin during cardiac resuscitation. For smoke inhalation patients, with suspected HCN poisoning, hydroxocobalamin is preferable to sodium thiosulfate because of its rapid onset of action. Inhaled amyl nitrite and intravenous sodium nitrite should be avoided because they generate methemoglobin that can further impair the oxygen-carrying capacity of blood hemoglobin if high levels of carboxyhemoglobin or methemoglobin are already present. The Paris Fire Brigade routinely administers hydroxocobalamin to smoke inhalation patients and published their experience in 2006 [53]. Of the 29 patients in cardiac arrest, 18 (62%) recovered with cardiac resuscitation and hydroxocobalamin treatment. The average time between hydroxocobalamin administration and recovery of spontaneous cardiac activity was 19 minutes. In 15 hemodynamically unstable patients not in cardiac arrest, 12 (80%) showed hemodynamic improvement (blood pressure >90 mm Hg) after hydroxocobalamin. The average time for hemodynamic improvement was 49 minutes from the start of and 29 minutes from the end of hydroxocobalamin infusion. In a second study, 28 of 42 patients (67%) admitted to the ICU with smoke inhalation and confirmed a posteriori HCN poisoning survived after hydroxocobalamin administration [54].

Respiratory symptoms and distress are not only related to oxygen delivery/utilization problems. Irritant, toxic gases can also cause tachypnea, stridor, and hoarseness as a result of upper and lower airway disease. Patients are at risk for developing progressive laryngeal edema with complete obstruction of the upper airway. Smoke inhalation further adds to this risk owing to heat and particulate matter exposure. Patients with laryngeal edema can be difficult to intubate and, if intubation is delayed, may require an emergency tracheostomy. However, not all patients require intubation [106]. Prompt inspection of the larynx with a laryngoscope is imperative [102]. Immediate intubation should be considered if there is evidence of significant upper airway edema or blisters. All patients with upper airway edema should be treated with nebulized racemic epinephrine and systemic corticosteroids. If edema is minimal and early intubation is not required, airflow can usually be maintained with positive pressure breathing administered by the use of continuous positive-airway pressure (CPAP) or bilevel positive-airway pressure (BiPAP). An inhaled mixture of helium and oxygen can also improve upper airway airflow by reducing turbulence as a result of its low density. If the clinical decision is not for immediate or early intubation [106], then patients with upper airway edema should be admitted to the hospital and closely monitored for signs of edema progression and the need for emergent intubation at a later time.

Lower airway involvement from irritant gas or smoke inhalation is
typically diagnosed by history and physical examination. However, additional diagnostic evidence can be provided by laryngoscopic or bronchoscopic demonstration of edema, hemorrhage, or carbonaceous material distal to the vocal cords. Inhalation injury to the smaller airways and lung parenchyma can be confirmed by Xenon 133 ventilation scanning \[107\] or noncontrast chest CT scans \[90,108\]. Inhalation injury on chest CT should be suspected with findings of ground-glass infiltrates (more central than peripheral). Sensitivity for both types of scans is high, but there are false positives, especially in patients with obstructive airway disease, and their value in determining the need for intubation, treatment, and prognosis has not been determined \[90,107,108\].

Lower airway involvement should be suspected on physical examination when wheezing is present or when spirometry or challenge testing demonstrates acute reductions in lung function, bronchodilator responsiveness, or airway hyperreactivity \[109–112\]. Acute bronchospasm should be treated with $\beta_2$-agonists. Ipratropium can be added if significant improvement is not obtained with a $\beta_2$-agonist alone.

In the presence of significant burn injuries, treatment with systemic corticosteroids is usually contraindicated, because their use is associated with increased mortality from sepsis \[113\]. Systemic corticosteroids should be reserved for severe upper airway obstruction, severe bronchospasm resistant to bronchodilator therapy, and failed extubation as a result of stridor or bronchospasm \[113\]. Low-dose inhaled corticosteroids have not been studied in large case series, but it is unlikely that they would negatively impact on mortality in burn patients. A placebo-controlled, double-blind, randomized control trial conducted in France showed that low-dose hydrocortisone reduced the need for vasopressors in severe burn patients \[114\]. Animal studies have shown that inhaled corticosteroids improve oxygenation and attenuate the development of acute lung injury following chlorine exposure \[115,116\]. Although inhaled corticosteroids are often given following chlorine and phosgene inhalation, there are no controlled clinical trials regarding their efficacy. Chest physiotherapy and frequent suctioning may be helpful in those patients with mucus plugs and thick secretions. Intubation may be necessary if bronchial secretions are excessive and frequent bronchoscopic suctioning needed.

Noncardiogenic pulmonary edema from acute lung injury (ARDS) is far less common than airway injury but should be suspected in patients with worsening oxygenation and increasing dyspnea. A chest radiograph should be obtained if signs of respiratory distress, abnormal breath sounds, or worsening hypoxemia are noted. Pulmonary edema or ARDS from inhalation injury typically presents as scattered, nodular alveolar infiltrates on chest radiographs, although large, diffuse, confluent infiltrates may occur as the illness progresses. Careful attention to fluid
and electrolyte balance is essential, especially if surface burns are present. If gas exchange abnormalities are severe, positive-pressure ventilation with CPAP or BiPAP may help to support adequate oxygenation. If there is no response or secretions are burdensome, then intubation and assisted ventilation are required. Nasotracheal intubation should be avoided because of the severe nasal inflammation that typically occurs following the inhalation of chemical irritants and because the smaller endotracheal tube diameters needed for nasotracheal intubation do not allow for the repeated bronchoscopic suctioning that may be needed if secretions become a problem. Positive end-expiratory pressure in the range of 5 to 10 cm H$_2$O may help to improve oxygenation in mechanically ventilated patients [117–119]. The use of systemic corticosteroids for the treatment of pulmonary edema or ARDS following toxic irritant inhalation remains controversial [120]. Again, there are no controlled clinical trials evaluating the efficacy of corticosteroid treatment. Most experts believe that corticosteroids are not useful as pulmonary edema, or ARDS typically resolves 48 to 72 hours after inhalation exposure, with most patients surviving if appropriate supportive treatment is given. However, whether corticosteroids might be useful for preventing the few that develop pulmonary bronchiolitis obliterans or pulmonary fibrosis remain to be determined. Experimental studies suggest that treatment to block inflammatory mediators and free radicals may be effective for smoke inhalation victims [121–123]. Recent examples include retrospective analyses of mechanically ventilated smoke inhalation patients, adult [124], and pediatric [125], demonstrating successful treatment with nebulized unfractionated heparin and N-acetylcysteine (Table 178.5). Other anticoagulants, including tissue plasminogen activator, antithrombin, and thromboxane have been studied to decrease inflammation and have shown promise in treating smoke inhalation [126]. However, prospective controlled clinical trials have not been conducted for any of the above experimental agents.

Secondary bacterial pneumonia can occur as a complication of irritant-induced airway or lung injury [127]. There is no evidence that the administration of prophylactic antibiotics reduces the incidence of secondary bacterial pneumonia. Antibiotics should be given only if pneumonia occurs, and the specific antibiotics chosen should be based on standard practice according to known community organisms and sensitivities until culture results return.
LONG-TERM COMPLICATIONS OF ACUTE INHALATION INJURY

Although most patients exposed to irritant gases or smoke will recover completely, others may develop long-term sequelae. The most common long-term complications are listed in Table 178.9. Some of these disorders may become evident in the days or weeks following acute exposure, whereas others may take months, or rarely even years, before clinical symptoms and signs become evident. Therefore, all patients with acute inhalational injury require medical follow-up for the potential development of these disorders, even if they are initially asymptomatic after resolution of acute signs and symptoms.

Some may develop a chronic cough syndrome, dyspnea, and/or wheezing following recovery from acute inhalation injury. Pulmonary function tests, chest radiographs, and high-resolution CT scans of the chest can be helpful for determining the etiology of chronic cough among such patients. When chest radiographs and chest CT scans are normal, the chronic cough is usually as a result of to asthma, RADS, bronchitis, rhinosinusitis, and/or gastroesophageal reflux [128,129]. Pulmonary function tests may be normal. Such patients could have rhinosinusitis, gastroesophageal reflux disease, and could also have RADS/irritant asthma. The diagnostic evaluation of such patients should be guided by a careful history and physical examination. RADS is characterized by immediate and persistent, nonspecific airway hyperreactivity following inhalation of a toxic substance in individuals with no prior history of cigarette smoking, allergen, or airway disease [130]. Irritant asthma is the more proper terminology if symptoms were not immediate or if there is a history of prior allergies, pulmonary disease, or smoking. When pulmonary function tests are normal, bronchial challenge testing (methacholine, histamine, mannitol, cold air, or exercise) may be
performed to evaluate airway hyperreactivity in patients suspected of having RADS or irritant asthma. Transient, self-limited bronchial hyperreactivity may occur in the weeks following irritant gas or smoke exposures, so the detection of early bronchial hyperreactivity may not always be predictive of RADS [109–112]. The evaluation of firefighters with heavy exposure to dust and irritant gases during the first days after the World Trade Center (WTC) collapse showed that bronchial hyperreactivity demonstrated by methacholine challenge testing after 1 month or 3 months after exposure was predictive of persistent airway hyperreactivity and RADS [112]. It can take months or years for the symptoms of RADS to resolve, and some patients may never have complete resolution. Treatment with an inhaled bronchodilator should be considered if a significant bronchodilator response is found. Even in the absence of a documented bronchodilator response, a trial should be considered if there is a history of symptoms with exercise, irritants, or change in temperature/humidity. Inhaled corticosteroids should be considered not only for symptom control but also for the possibility, albeit unproven concept, that early treatment may prevent progression or lead to resolution [131].

If symptoms persist, serial measurements of spirometry, lung volumes, and diffusion capacity should be assessed to determine whether there is accelerated decline in lung function, hyperinflation, bronchiolitis obliterans, emphysema, or pulmonary fibrosis. A study of more than 12,000 firefighters and EMS workers exposed to dust and gases from the September 11, 2001, attack on the WTC found that the decline in lung function during the first 6 to 12 months after the attack was 12 times the expected annual decline and even more important for the majority of those exposed to this decline persisted for the next 6 years [132]. Another study of firefighters exposed to WTC dust and gases demonstrated that interstitial pulmonary fibrosis was exceedingly rare and that airway obstruction was probable cause of the persistent lung injury [133].

Bronchiolitis obliterans is a rare but particularly ominous complication following the inhalation of certain toxic gases, particularly NO₂, other oxides of nitrogen, SO₂, mustard gas, and/or smoke [134–138]. Inhaled toxicants that can produce bronchiolitis obliterans are listed in Table 178.10. Bronchiolitis obliterans can take two forms following acute inhalation injury. The first form is manifested by the acute onset of fever, chills, cough, dyspnea, and generalized lung crackles that develop 2 to 8 weeks after acute exposure to an offending gas, as discussed in “Nitrogen Oxides” section. Chest radiographs or high-resolution CT scans typically show a diffuse “miliary” pattern of small nodules and/or areas of ground-glass inflammation. Although lung biopsies are usually not necessary to make the diagnosis with a history of acute inhalation injury, they show a proximal bronchiolitis with occlusion of the bronchioles by inflammatory
exudates and fibrin, but without organizing pneumonia [139]. Bronchiolitis obliterans can be life threatening if untreated, but, for many, may improve or resolve with systemic corticosteroid therapy [139]. It is recommended that patients with this form of bronchiolitis obliterans be treated with 40 to 60 mg of prednisone daily for at least 2 months, with the dose tapered after all symptoms and radiographic findings resolve. The second type of bronchiolitis obliterans occurs in patients who have persistent cough and dyspnea with an obstructive ventilatory impairment on pulmonary function tests that does not respond to inhaled corticosteroids or bronchodilators [139,140]. Chest radiographs may appear normal, but high-resolution CT scans of the chest often show hyperinflation and air trapping. Lung biopsy may be necessary to make a definitive diagnosis and typically shows a pure constrictive bronchiolitis. This form of bronchiolitis obliterans is usually not responsive to systemic corticosteroid therapy, and the prognosis for improvement is poor. Patients affected with this form of bronchiolitis obliterans may get progressively worse and suffer life-long disability. The administration of prophylactic corticosteroids to prevent bronchiolitis obliterans following inhalation injury is controversial with treatment effects in either direction [141,142].

INTRODUCTION

Radiographic examination of the critically ill patient in the intensive care unit (ICU) or coronary care unit (CCU) is often necessary to follow the patient’s progress or changes in status after admission or after surgery. Radiographic examinations are requested to evaluate the course of the primary disease and to diagnose complications that may ensue. The bedside chest radiograph has been shown to alter management 85% of 258 consecutive radiographs analyzed by Palazzetti and colleagues [1]. A similar retrospective study analyzing 1,354 radiographs from a respiratory ICU found a 34.5% incidence of new or increased abnormalities or tube or catheter malpositions [2]. These studies suggest that routine daily radiographic examinations frequently demonstrate unexpected or changing abnormalities, many of which prompt changes in clinical management. In 2013, American College of Radiology published appropriateness criteria for the need of ICU studies advising that a portable chest radiograph is appropriate after placement of an endotracheal tube, central venous line, Swan–Ganz catheter, nasogastric tube, feeding tube, or chest tube or if a clinical indication mandates chest radiography in a stable or ventilated patient [3].

Critically ill patients in the ICU or CCU often cannot take advantage of radiologic investigations that are readily available to mobile patients. Because some of these patients cannot be transported while their circulatory functions are labile and they are connected to
electrocardiogram monitors, ventilators, catheters, and surgical appliances, usually the only examination that is readily available to them is the portable bedside radiographic examination. The chest radiograph is especially important because physical examination to determine the presence of complications such as atelectasis, pneumothorax, pneumonia, or pulmonary edema is limited in the intubated and ventilated patient.

The main advances in portable screen-film radiographic examinations include the advent of computed radiography and flat panel detectors [4]. Computed radiography technology uses a photostimulable barium halide phosphor cassette similar to that used in screen-film radiography. After exposure, the cassette is transported to a computed radiography reader device, which is scanned by a laser; the image is then available in digital soft copy format. The main advantages include the reduced need for cassette handling leading to improved workflow and the ability to manipulate the image after acquisition to improve visualization of subtle structures (e.g., a central venous catheter tip). Flat panel technology is based on thin layers of amorphous silicon thin-film transistors (TFTs) deposited on a piece of glass. The TFT layer is coupled with an X-ray absorptive layer. Because the silicon film transistors are thin, the X-ray absorptive layer can be thick, leading to increased X-ray detection efficiency. This development has addressed the limitation of long exposure times inherent to prior iterations of radiographic systems and has thus enabled a reduction in radiation dose while continuing to possess the described advantages of computed radiography. Both flat panel and computed radiography imaging systems can now be used for portable chest radiographic examination.

Interpretation of portable examinations is fraught with pitfalls. Magnification of the cardiac silhouette cannot be eliminated because of the short tube–detector distance and the often supine position of the patient. Signs used to evaluate pulmonary venous hypertension are not valid on the supine radiograph. Furthermore, the meniscus of a pleural effusion is often not visible using supine or semi-erect radiographic positioning. Radiographs are often acquired after a poor inspiratory effort because of the patient’s inability to follow breath-hold instructions. As a result, the appearance of parenchymal abnormalities is difficult to evaluate. Increased inflation of the lung may cause the opacities to appear less dense, but the apparent improvement secondary to increased aeration does not correspond to a true improvement. The reverse situation can occur as well, particularly after a patient has been extubated (Fig. 179.1).
The degree of inflation of the lung may cause pulmonary opacities to appear more or less dense indicating an apparent disimprovement which is in fact secondary to decreased aeration (e.g., the removal of an endotracheal tube). This is demonstrated on this anteroposterior portable chest radiograph of a 70-year-old male who is day 2 after uncomplicated mitral valve repair. The first radiograph (A) demonstrates a low lying endotracheal tube tip in the lower trachea (arrow), two satisfactorily positioned right internal jugular venous catheters, intact sternotomy wires, two mediastinal drains, and moderate cardiomegaly. Five hours later (B), the endotracheal tube has been removed because of clinical stability and as a result, lung density increases due to the absence of mechanical ventilation.
Endotracheal Tubes

The location of endotracheal tubes should be checked as soon as possible after insertion (see Chapter 1). To evaluate the position of the tube properly, Goodman et al. [5] showed that one must evaluate the head and neck position simultaneously because tube position can change with flexion and extension of the neck [6] by as much as 4 cm [5,7]. If the radiograph includes the mandible, the following guidelines may be of use:

1. When the inferior border of the mandible is at or above C4, the tip should be 7 ± 2 cm from the carina.
2. When the inferior border of the mandible is at the C5 to C6 levels, the tip of the tube should be 5 ± 2 cm from the carina.
3. When the inferior border of the mandible is at T1 or below, the tip of the tube should be 3 ± 2 cm from the carina.

If, however, the mandible is not visible, and the technologist has ensured that the head is in a neutral position, an endotracheal tube position 5 ± 2 cm from the carina is acceptable (Fig. 179.2). When the tube is too high, it may slip into the pharynx. If it is just below the vocal cords, its inflated cuff can cause glottic or subglottic edema, ulceration, and, ultimately, scarring. If it is too low, it can enter a bronchus and cause atelectasis of the lung supplied by the obstructed bronchus (Fig. 179.3).
FIGURE 179.2 Correct endotracheal tube position. Anteroposterior portable chest radiograph of a 70-year-old male who is day 1 after mitral valve repair. The radiograph demonstrates appropriate endotracheal tube position in the lower trachea 3 cm from the carina (arrow), two satisfactorily positioned right internal jugular venous catheters, intact sternotomy wires, two mediastinal drains, acute perihilar “batwing” opacities indicating pulmonary edema which resolved after diuresis (Fig. 179.1) and moderate cardiomegaly.
Anteroposterior chest radiograph of a 25-year-old male admitted to the ICU after a motor vehicle accident. The radiograph demonstrates the tip of the endotracheal tube in the right main bronchus (arrow), causing right upper lobe atelectasis; in addition, there is complete collapse of the left lung owing to a large pneumothorax which has been treated with emergent left chest tube placement, the tip of which is in satisfactory position. ICU, intensive care unit.

Ideally, the tube should be one-half to two-thirds the width of the trachea, and the inflated cuff should fill the trachea without causing the lateral walls to bulge. Repeated overdistension of the cuff on chest film, despite careful cuff inflation to the minimal leak level may predispose to tracheomalacia (Fig. 179.4) [6].
Immediately after intubation, and especially after difficult intubation, an image should be obtained to define the position of the endotracheal tube. The radiologist should also look for signs of perforation of the pharynx, such as new subcutaneous emphysema, pneumomediastinum, and pneumothorax. Dislodging of teeth, dental caps, and portions of dentures into the tracheobronchial tree has been reported after intubation. If this is suspected, a foreign body in the tracheobronchial tree should be carefully sought.

Tracheostomy Tubes
The tip of the tracheostomy tube should be located one-half to two-thirds of the way between the stoma and the carina. Unlike the endotracheal
tube, the tracheostomy tube does not change position with flexion and extension of the neck. The tracheostomy tube should be evaluated to determine its inner diameter (which should be two-thirds that of the tracheal lumen); its long axis (which should parallel the tracheal lumen); the location of its distal end (Fig. 179.2) (which should not about the tracheal wall laterally, anteriorly, or posteriorly); and for development of new pneumothorax, pneumomediastinum, or subcutaneous emphysema, which may indicate tracheal rupture.

Central Venous Catheters

Central venous catheters should be evaluated to ensure accurate central venous pressure measurement and central venous drug delivery. The catheter tip should be located at the superior cavoatrial junction. The intersection of the bronchus intermedius with the right heart border and the inflection of the right heart border are the closest radiographic landmarks to the cavoatrial junction. When these landmarks are not identifiable, the most uniformly visible radiographic landmark is the carina; the superior cavoatrial junction is approximately 4 cm above this structure (Fig. 179.5) [8]. Complications of central venous catheter placement include infection, vascular perforation or dissection, inadvertent arterial cannulation (Fig. 179.6A), and cardiac perforation, leading to cardiac tamponade (Fig. 179.6B) and catheter fragment embolization.
Junction of internal jugular vein and right subclavian vein. Veins shown in relation to the first rib. The junction of the internal jugular and right subclavian veins (long arrow) occurs at approximately the level of the first rib (short arrow). The central venous pressure line should be at or beyond this point to measure true venous pressure. (Drawing by Mary Cunnion).
FIGURE 179.6 A: Central line complications. Inadvertent arterial cannulation. Anteroposterior chest radiograph in a 50-year-old female day 1 after hysterectomy and central line insertion who
complained of dizziness. The central venous catheter crosses the midline consistent with an intra-arterial course (arrow), an iatrogenic right pneumothorax has been treated with chest tube placement. A subsequent CT confirmed catheter position in the right subclavian artery and a posterior circulation cerebral infarct owing to occlusion of the right vertebral artery. B: Central line complications. Portable anteroposterior view of a different patient with pulmonary edema in whom a central venous pressure line extends from the left subclavian vein. The line entered the pericardium (arrows) and caused tamponade from the bleeding resulting from the vascular perforation. CT, computed tomography.

Swan-Ganz Catheters

Swan-Ganz catheters are used to perform right heart catheterizations [9]. Ideally, the tip of the Swan-Ganz catheter should be located in the right or left branch of the pulmonary artery (Fig. 179.7). Occasionally, the tip may be malpositioned (Fig. 179.6); a radiograph should be routinely taken to check its position. If the catheter tip is more than 3 cm from the midline, the catheter could potentially produce pulmonary infarction (Fig. 179.8A–C) by blocking the artery directly or from a clot in or around the tip. Other rare complications include perforation of the pulmonary artery, the resulting focal hemorrhage leading to the formation of “traumatic pseudoaneurysm” (Fig. 179.8D), balloon rupture, and pulmonary artery-bronchial tree fistula. Once correct position is confirmed radiographically, clinical criteria can be used to confirm ongoing correct position which include >1.25 mL volume of air required to insufflate the catheter tip balloon and obtain a pulmonary capillary wedge pressure tracing and the absence of >1 cm migration from initial catheter position according to the centimeter markings from the catheter hub [10].
FIGURE 179.7 Thoracic CT scout (A) and axial images (B) in a 52-year-old female with dilated cardiomyopathy shows a right internal jugular approach Swan–Ganz catheter with its tip in the left lower lobar pulmonary artery (arrow). CT, computed tomography.

FIGURE 179.8 A–D: Infarction caused by Swan-Ganz catheter. A: Preoperative posteroanterior view of the chest shows bilaterally clear lung parenchyma. B: Postoperative posteroanterior view of the chest shows overly distal position of the Swan-Ganz catheter. An area of density (arrow) surrounds the tip of the catheter, representing a pulmonary infarct in the area supplied by the occluded artery. C: Posteroanterior film after 5 days shows a persistent left lower lobe density (arrow)—the resolving infarct. Right pleural effusion is also present. D: Note tip of Swan-Ganz catheter line at periphery of right upper lobe pulmonary artery and showing a round opacity representing “traumatic pseudoaneurysm” (arrow).

Intra-Aortic Balloon Pump
The intra-aortic balloon pump (IABP) was designed to improve cardiac function and coronary perfusion in a setting of cardiogenic shock, and this remains the major indication for its use [11]. Ideally, the tip of the IABP should be positioned at the level of the aortic arch below the origin of the left subclavian artery to augment coronary artery perfusion during diastole maximally without occluding the subclavian and cerebral vessels (Fig. 179.9). A position too low in the thoracic aorta may limit its effectiveness and can give rise to occlusion of the abdominal aortic branches. On the chest radiograph, the ideal IABP position was defined as below the aortic arch, between T2 and T5 vertebrae [12]. Complications related to IABP placement include major vessel obstruction (Fig. 179.10), embolization from a clot formed in or around the catheter, and aortic dissection with balloon rupture.

**FIGURE 179.9** Correct IABP position. The tip of the IABP should be positioned at the level of the aortic arch below the origin of the left subclavian artery (arrow) to augment coronary artery perfusion during diastole maximally without occluding the subclavian and cerebral vessels. IABP, intra-aortic balloon pump.
FIGURE 179.10 Sagittal (A) and axial (B) CT images of a 41-year-old male with a myocardial infarct requiring intra-aortic balloon pump placement demonstrates appropriate distal tip position distal to the left subclavian artery origin of the aortic arch (arrows). The balloon is inflated during image acquisition, and is shown to be too long, descending below the coeliac artery origin resulting in splenic infarction. CT, computed tomography.

Chest Tubes

Chest tubes (thoracostomy or pleural drainage tubes) are used to drain either fluid or air from the pleural space (see Chapter 8). If placed for a pneumothorax, the tube tip should be projected over the lung apex where pleural air typically collects on the chest radiograph; if placed to drain a pleural effusion, the tube should be projected over the posterior lower pleural space (Fig. 179.11A, B). If a wide bore chest tube is used, the side hole of the tube (where there is an interruption in the opaque marker) should be seen within the pleural space. If a locking pigtail catheter is used, the catheter should form a round loop in the pleural space, thus ensuring sidehole position within the pleura because sideholes are typically located only in the region of the pigtail; if present, a radio-opaque marker indicates the position of the most distal sidehole.
FIGURE 179.11 A, B: Satisfactory pleural drainage catheter position. Chest radiographs of a 33-year-old female with dyspnea secondary to stage 4 ALK mutant lung carcinoma with a malignant right pleural effusion. A right pleural catheter was placed with symptomatic improvement; the pigtail and its sideholes are shown within the right lateral pleural space (arrow). A small right lateral pneumothorax is likely owing to ex vacuo phenomenon in a chronically atelectatic lung because of the large right effusion. ALK, anaplastic lymphoma kinase.

Nasogastric Tubes

The tip of the nasogastric tube should be visible below the diaphragm projected over the expected location of the stomach. Malposition in the esophagus or bronchi should be excluded radiographically prior to nasogastric tube use (Fig. 179.12A, B). Malposition in the lungs can rarely lead to bronchopleural fistula formation (Fig. 179.12C).
Nasogastric tube malposition. A: Anteroposterior chest radiograph in a patient requiring nasoenteric feeding. The initial radiograph demonstrated too proximal a tube tip position in the lower esophagus (arrow). B: A repeat anteroposterior radiograph after nasogastric tube repositioning confirms satisfactory position in the stomach with the distal tip coiled in the gastric fundus (arrow). C: Posteroanterior chest radiograph in a 57-year-old female with supraglottic squamous cell carcinoma and recurrent aspiration pneumonia requiring nasoenteric feeding. A nasogastric tube was placed at the bedside, and a radiograph demonstrates malposition with the distal tip of the nasogastric tube projected over a large right pneumothorax indicating perforation of the lung owing to endobronchial placement of the tube.

Transvenous Pacemakers

Pacemaker leads are passed under fluoroscopic guidance into the right atrium, apex of the right ventricle, and/or through the coronary sinus into the left ventricular cardiac vein; the latter is used for biventricular pacing in severe heart failure [13] (see Heading V). Films should be checked for breaks or fractures in the wire (Fig. 179.13). A lateral view should be obtained to ascertain that the right ventricular pacemaker tip is
directed anteriorly 3 to 4 mm beneath the pericardial fat [14]. A posteriorly directed tip on the lateral view, coupled with a cephalad direction in the anteroposterior (AP) view, suggests that the pacer is in the coronary sinus or a tributary [15]. Projection of the pacemaker tip anterior to the pericardial fat stripe suggests myocardial perforation [14]. Subcutaneous emphysema may signify air entrapment in the pulse generator pocket. This can produce a system malfunction with unipolar pulse generators [16].

Assessment of the position of the tubes and lines with computed tomography (CT) is precise and usually achieved with a combination of axial, coronal, and sagittal reformatted images.
EVALUATION OF THE LUNG PARENCHYMA

Densities of the Lung Parenchyma

Pulmonary parenchymal densities in the critically ill patient may be caused by either infectious or noninfectious conditions, such as atelectasis, cardiogenic pulmonary edema, acute respiratory distress syndrome (ARDS), pulmonary infarction, or contusion. Radiologic evaluation to determine whether parenchymal densities are secondary to pulmonary edema, or other causes, or a combination is often necessary so that appropriate therapy can be started.

Evaluation of densities in the retrocardiac area was traditionally performed using an overpenetrated radiograph before the introduction of computed radiography. Computed radiography and flat panel detector technology have helped overcome these challenges owing to the ability of the radiologist to manipulate image from computed radiographic images digitally and the improved X-ray detection efficiency of silicon film transistors [4].

Congestive Heart Failure and Pulmonary Edema Owing to Pulmonary Venous Hypertension

Radiography

Elevation of pulmonary venous pressure, irrespective of cause, produces a sequence of radiologic findings. When pulmonary venous pressures rise above normal, pulmonary vascular redistribution occurs [17], producing distention of the upper lobe vessels with a concomitant decrease in caliber of those in the lower lobe in the upright patient. For patients in the supine position, the equivalent of the upper lobe vessels is the anterior or ventral pulmonary vessels and the equivalent of the lower lobe vessels is the posterior or dorsal vessels. The change in caliber of the vessels in the supine position may be discernible on a cross-table lateral film of the chest.
At pulmonary capillary wedge pressures of 20 to 25 mm Hg, lymphatic drainage is exceeded and the alveolar interstitium, bronchovascular interstitium, interlobular septa, and subpleural tissues fill with fluid. The visible radiologic changes include:

1. Thickening of the interlobular septa (Kerley A and B lines) (Fig. 179.14A, B).
2. Peribronchial cuffing: The bronchial walls (which normally manifest as thin well-defined radiodense rings when imaged en face) become ill-defined and more radiodense (Fig. 179.2).
3. Blurring or haziness of the perivascular outlines (Fig. 179.14C)
4. Widening of the pleural layer over the convexity of the lungs secondary to the presence of fluid in the subpleural space
5. Pulmonary vascular redistribution (Fig. 179.14C)

**FIGURE 179.14** Pulmonary edema. A: Frontal chest radiograph in a 54-year-old male with mitral valve regurgitation demonstrates enlargement of the left atrium (arrow). B: Magnified view of the same patient’s chest radiograph confirms thickening of the interlobular septa, likely indicating chronic pulmonary edema. C: Frontal chest radiograph of a 63-year-old demonstrates blurring of the perivascular outlines,
diffuse ground glass opacity, and enlargement of the upper lobe pulmonary vein redistribution consistent with pulmonary edema. D: Frontal chest radiograph of an 85-year-old female with mitral regurgitation and dyspnea demonstrates asymmetric ground glass opacity in the right lung likely secondary to a flail posterior mitral leaflet.

At pulmonary capillary wedge pressures of 25 to 40 mm Hg, fluid fills the alveolar spaces and alveolar edema is seen. The air space consolidation may extend to the subpleural zone, or the more characteristic butterfly or bat-wing edema pattern may be seen (Fig. 179.2).

Unilateral pulmonary edema in the ICU may relate to patient positioning; however, acute unilateral pulmonary edema is a typical manifestation of acute mitral regurgitation (Fig.179.14D) [18]. Unilateral diminution in pulmonary blood flow, as seen in Swyer–James syndrome, right or left pulmonary artery thromboembolism, and surgical corrections of congenital heart disease (e.g., shunts for tetralogy of Fallot), are other causes of unilateral edema.

Atypical patterns of congestive failure and pulmonary edema have been described in patients with chronic pulmonary disease [19]. It is postulated that the thick-walled spaces in which thickened fibrous septa replace normal alveolar walls impair collateral ventilation and prevent dispersion of edema fluid throughout the lungs [19]. Fluid is then trapped in relatively larger spaces that have replaced normal alveoli. Shadows produced do not coalesce, and the images are seen on radiographs as miliary nodular patterns. The other two patterns, interstitial and reticular, are also seen without chronic lung disease.

Pulmonary edema can be owing to cardiac or noncardiac causes. Different radiologic indices distinguish between hydrostatic (cardiac) edema, overhydration pulmonary edema, and edema secondary to increased capillary permeability (see “Acute Respiratory Distress Syndrome” section) [20]. In overhydration edema (e.g., edema secondary to renal failure), the cardiac output is large, and, consequently, pulmonary blood flow is large. All vessels are recruited, and no redistribution of flow occurs. Because blood volume is also increased, the vascular pedicle, azygos vein, and hilar vessels are large. In pure capillary permeability edema, there is no increase in blood volume, and therefore the vascular pedicle and azygos vein remain normal in size; no signs of pulmonary venous hypertension are present, and heart size is also normal. When different types of edema coexist, edema may occur at lower left atrial pressures, and wedge pressure readings may be low or only slightly elevated [21].
Computed Tomography

Although not required in the diagnosis of pulmonary edema, specific CT features are observed on CT:

1. Thickening of the interlobular septa (Fig. 179.15)
2. The dorsal vessels become progressively narrower because of the increase in pulmonary venous pressure.
3. Diffuse ground glass opacity throughout the lung parenchyma
4. Pleural effusions.

**FIGURE 179.15** Interlobular septal thickening.
Axial CT images of two patients, one with acute pulmonary edema owing to fluid overload (A) and another with chronic pulmonary edema because of mitral valve regurgitation (B). The secondary pulmonary lobules that are outlined by a thin septum containing lymphatic channels and veins are not normally visible on CT, but the edematous septa become thickened in the setting of pulmonary edema and therefore become perceptible on CT (arrows). CT, computed tomography.

Acute Respiratory Distress Syndrome

ARDS is a progressive hypoxic condition with radiographic bilateral lung infiltration, which is not derived from hydrostatic edema. Numerous diseases cause ARDS, but the common denominator is diffuse alveolar damage [22]. The pathologic alterations with corresponding radiologic changes occur 12 to 24 hours after the first appearance of respiratory
symptoms. Insidious accumulation of fluid in the extravascular space occurs.

**Radiography**

The corresponding radiologic picture includes perihilar, perivascular haziness with peribronchial cuffing. Only occasionally are Kerley A and B lines seen; in one series, they were noted in only five of the 75 cases [23]. During the acute stage, the alveoli also become inhomogeneously filled with a proteinaceous and often hemorrhagic cell-containing fluid. Hyaline membranes form in the alveoli and sometimes in the alveolar ducts. The radiologic picture is one of heterogeneous or confluent ground glass opacity that is not rapidly reversible (Fig. 179.16A). The course of ARDS is highly variable. In some patients, reabsorption of the exudates is complete within a few days, thereby producing radiologic clearing of the densities. In some, there is a delayed clearing of the exudates, with a corresponding delay in clearing of the radiologic picture. In a third group, progressive fibrosis occurs, predominantly in the nondependent lung, where barotrauma from mechanical ventilation is worst.

**FIGURE 179.16** Acute respiratory distress syndrome: Sequential chest radiographs of a 54-year-old male admitted to the ICU with hypoxia after femorofemoral bypass surgery. Initial chest radiography demonstrated diffuse ground glass opacity which persisted for 2 months (A), 1-year follow-up chest radiograph (B) performed to assess the cause of an ongoing oxygen requirement confirmed apical predominant pulmonary fibrosis consistent with the long-term sequelae of acute respiratory distress syndrome. ICU, intensive care unit.

After the first week, the radiologist’s main concern is the recognition of
superimposed complications, such as pulmonary infections, oxygen toxicity, barotrauma, and pulmonary embolism with infarction. When clinical signs and symptoms of infection are present and the radiographic picture deteriorates, pneumonia should be suspected. Development of cavities and a change in the character of the densities should lead to suspicion of superimposed abscess, infarction, or cardiac failure. Only direct hemodynamic measurements of the pulmonary capillary wedge pressure provide a dependable means of detecting superimposed failure in cases of ARDS [24]. Radiographic findings in the chronic phase of ARDS serve as independent predictors of mortality and include cyst formation, ground glass opacity, and bronchiectasis (Fig. 179.16B) [25].

Computed Tomography

The following specific features are observed on CT [26]:

1. Acute phase
   a. Dense consolidation in the dependent portions of the lung (Fig. 179.17A)
   b. Diffuse ground glass opacity throughout the lung parenchyma (Fig. 179.17B)
   c. Bronchiectasis is occasionally observed

2. If parenchymal abnormalities persist after the acute phase, findings include:
   a. Pulmonary cysts in the nondependent lung (Fig. 179.17C)
   b. Reticulation and ground glass opacity in the nondependent lung (Fig. 179.17D)
Acute respiratory distress syndrome: Axial CT images of a 54-year-old male admitted to the ICU with hypoxia after femorofemoral bypass surgery. Initial chest radiography and CT demonstrated diffuse ground glass opacity (A) which persisted for 2 months (B), 1-year follow-up chest CT performed to assess the cause of an ongoing oxygen requirement confirmed nondependent apical predominant pulmonary fibrosis (C,D) consistent with the long-term sequelae of acute respiratory distress syndrome. CT, computed tomography; ICU, intensive care unit.

Atelectasis and Pneumonia

Radiography

Atelectasis is easily diagnosed when a characteristic linear or triangular density is accompanied by volume loss (shift of fissures or mediastinum or diaphragmatic elevation, or both). Densities that fall between these categories, however, such as scattered opacities, are often indistinguishable from pneumonia on a single study.

In the presence of opacities that are not readily diagnosed as atelectasis, pneumonia should be strongly considered. Bronchial aspirates for culture should be obtained from the lung periphery, with care to bypass the upper airway because the central airways become readily colonized after placement of a tracheostomy or endotracheal tube [27].

Computed Tomography
Evidence of volume loss, such as hyperexpansion of adjacent lung or migration of mediastinal structures toward the atelectatic lung, favors atelectasis on both contrast-enhanced and noncontrast-enhanced thoracic CT. Contrast-enhanced CT helps to differentiate between the normal enhancement pattern of atelectatic lung and the expected hypoenhancing appearance of pneumonia.

Aspiration

The extent and severity of pulmonary injury after aspiration of gastric contents depend on the volume and character of the aspirated material (see Chapter 170). Aspiration pneumonitis (Mendelson syndrome) is a chemical injury caused by the inhalation of sterile gastric contents [28]. Pathologically, the lungs show areas of atelectasis within minutes; up to 1 hour after aspiration, however, only mild microscopic abnormalities are present (interstitial edema with capillary congestion). These progress to complete desquamation of the bronchial epithelium and polymorphonuclear leukocyte infiltration of the airways (bronchiolitis). Alveolar spaces fill with fluid, red blood cells, and polymorphonuclear leukocytes, progressing to consolidation in 24 to 48 hours. Formation of hyaline membranes occurs by 48 hours and organization or resolution within 72 hours [29,30].

Radiography

Findings of aspiration pneumonitis are often concurrent with those of aspiration bronchiolitis and include airway thickening with ground-glass opacities in centrilobular and peribronchovascular distribution. Aspiration pneumonia is an infectious process caused by the inhalation of oropharyngeal secretions that are colonized by pathogenic bacteria [28], which manifests as segmental or lobar consolidation. In supine patients, typically, the posterior segments of the upper lobes and superior segments of the lower lobes are involved; and in upright patients, the posterior segments of the lower lobes are involved (Fig. 179.18) [31,32].

Computed Tomography

CT findings usually consist of multiple patchy and ill-defined consolidations of relatively low-density with posterobasal predisposition (Fig. 179.18). Occasionally, consolidation contains areas of fluid density or cavities as a sign of necrotizing pneumonia or abscess.
Diffuse aspiration bronchiolitis is characterized by chronic inflammatory reaction to repeatedly aspirated foreign particles in the bronchioles. Patients with esophageal conditions such as achalasia, Zenker’s diverticulum, or esophageal carcinoma are at risk for aspiration bronchiolitis. These patients often develop moderate to marked dilatation of the esophagus, with associated signs and symptoms such as dysphagia, regurgitation, and aspiration. At thin-section CT, aspiration bronchiolitis manifests as unilateral or bilateral foci of branching areas of increased attenuation with a tree-in-bud appearance or as mottled, poorly defined acinar areas of increased attenuation (Fig. 179.18). Consolidation is not a major radiologic finding of aspiration bronchiolitis. Esophageal dilatation with an air-fluid level may also be present.

**FIGURE 179.18** A: Chest radiograph of a 53-year-old male who experienced an aspiration event in the early postoperative period after colectomy. Left lower lobe ground glass opacities represent aspiration pneumonitis and are better delineated on CT (B). C: aspiration bronchiolitis in a 63-year-old female with recurrent episodes of silent aspiration. Aspiration bronchiolitis manifests as unilateral bilateral tree-in-bud nodules.

**Fat Embolism**

Fat embolism usually follows trauma associated with fracture, but conditions such as severe burns, diabetes mellitus, fatty liver, pancreatitis, steroid therapy, sickle cell anemia, surgery for prosthetic hip placement, and acute osteomyelitis can also result in fat embolism. Most of the fat is believed to originate from the bone marrow, entering the circulation via torn veins in the injured area and, to a lesser extent, through the lymphatic system. Fats are then transported to the lungs in the form of neutral triglycerides. The fat globules also appear to induce
platelet and erythrocyte aggregation and stimulation of intravascular coagulation.

Continuous fat embolization, conversion of triglycerides to fatty acids, and intravascular coagulation occur as an ongoing process over 1 to 3 days. Emboli pass from the pulmonary circulation into the systemic circulation and lodge in different organs, notably the brain, kidney, and skin.

The chest radiographic manifestation of fat embolism is that of acute pulmonary edema which develops within 72 hours of trauma [33,34]. The pulmonary opacities clear in 7 to 10 days but may take 4 weeks to resolve completely [34]. Acute cor pulmonale with cardiac failure may also be seen.

Computed Tomography

Although CT is not typically used to diagnose fat embolism, reported CT findings include scattered ground-glass opacities, consolidation, and centrilobular nodules in the order of frequency [35].
ABNORMALITIES OF THE PLEURA, MEDIASTINUM, AND DIAPHRAGM

Pleural Effusion

Radiography

The radiographic appearance of fluid in the pleural space is the same whether the fluid is serous, chylous, purulent, or sanguinous. The degree of opacity of the effusion depends on the amount of fluid and presence or absence of underlying pulmonary disease. It is easily identifiable when tangential to the X-ray beam as a homogenous opacity that is free from lung markings, displaces the lung, and is most often located in the dependent portion of the thorax, with a meniscus along its superior margin. However, when the X-ray beam is parallel to the meniscus of the effusion, it appears as a homogeneous area of increased density in the thorax through which vascular markings may be seen.

Free pleural fluid is not confined to any portion of the thoracic cavity, and the distribution changes with patient position. Distribution is influenced by gravity, capillary action, and resistance of the underlying lung to expansion. In the upright position, the fluid collects first in the posterior costophrenic sulcus and subsequently in the lateral costophrenic sulcus. The typical meniscal configuration of pleural fluid (Fig. 179.19) is attributed to several factors, including capillary attraction drawing the fluid superiorly between the visceral and parietal pleural surfaces, the relation of the fluid surface to the radiograph beam, the greater retractility of the lung periphery, and the tendency of the lung to preserve its shape while recoiling from the chest.
Pleural effusion in a 35-year-old female after cholecystectomy demonstrates a homogenous right basal opacity with a curvilinear upper meniscus (arrow) consistent with right pleural effusion.

Subpulmonic pleural fluid is the typical pattern of free fluid collection in the upright position if no pleural adhesions are present [36]. Radiologically, the fluid presents as an opaque density, parallel to the diaphragm and simulating an elevated hemidiaphragm (Fig. 179.20). Subpulmonic effusion is recognized in the posteroanterior (PA) film when the apex of the pseudodiaphragmatic shadow peaks more laterally than usual. The pulmonary vessels in the lung posterior to the subpulmonic collection cannot be seen through the pseudodiaphragmatic contour because of the greater density of the fluid collection. On the left side, there is increased distance between the gastric bubble and the base of the lung. Often, the costophrenic sulcus is blunted.
The appearance of interlobar fluid depends on the shape and orientation of the fissure, location of fluid within the fissure, and direction of the radiograph beam. Often, an elliptic or rounded, sharply marginated density is identified on PA or lateral films and has been described as a “pseudotumor” (Fig. 179.21).
decubitus view (right side down) shows layering of the pleural fluid (arrow). C: Right lateral decubitus view shows layering of pleural fluid and tracking into the minor fissure (arrows). Note bilateral apical caps (arrowheads).

A lateral decubitus view can be obtained to confirm the presence of pleural effusion, rule out a parenchymal process coexisting with an effusion, or quantify the amount of fluid in the pleural cavity. In the lateral decubitus view, fluid forms an opacity parallel to the thoracic wall (Fig. 179.22). When a decubitus view cannot be obtained for a completely immobile patient, an ultrasonographic evaluation can be performed. Sonographically guided thoracentesis enhances the likelihood of a successful tap in these cases and when the fluid is loculated.

**FIGURE 179.22** Loculated pleural effusion and acute respiratory distress syndrome. Chest radiograph in a 42-year-old male with H1N1 influenza pneumonia and acute respiratory distress syndrome requiring prolonged extracorporeal membrane oxygenation resulting in pleural effusions, PIE and pneumothoraces. A–C: Chest radiography and CT demonstrated a loculated right major fissural pleural effusion (arrowheads) and air-filled perivascular spaces that are separate from the airways and the pleural space (arrows) consistent with PIE. In addition, there are bilateral apical chest drains and a correctly positioned tracheostomy tube. CT, computed tomography; PIE, pulmonary interstitial emphysema.
Pleural effusion occurs quite frequently in the first week after thoracic or abdominal surgery (Fig. 179.19). After pneumonectomy, increasing amounts of fluid are noted to accumulate in the thorax. This accumulation occurs over a period of 1.5 to 2 months after surgery, ultimately leading to complete hemithoracic opacification by 2 months (Fig. 179.23) [37].

![Expected radiographic changes post-pneumonectomy: Serial chest radiographs (A–D) immediately, 2 weeks, 2 months, and 1 year after pneumonectomy demonstrate gradual opacification of the pneumonectomy space with progressive resolution of pleural air.]

**Computed Tomography**

Although it is rarely necessary to perform CT to diagnose pleural effusion, it may be used as a tool to differentiate between a simple pleural effusion, hemothorax, or an empyema. A simple pleural effusion is typically located in the dependent portion of the pleural space, is homogenously low in attenuation, and does not enhance. A hemothorax is higher in attenuation, may exhibit internal layering, and may not lie in the
dependent portion of the lung. The CT features of empyema are discussed in the next section.

**Empyema and Peripheral Lung Abscess**

An intrathoracic fluid-containing cavitary lesion adjacent to the chest wall may represent either a lung abscess or an empyema.

**Lung Abscess**

**Radiography.** Conventional radiography may show a thick-walled cavity and an air fluid level within the cavity. There may be associated consolidation or atelectasis.

**Computed Tomography.** Typically, CT is performed to differentiate between lung abscess and empyema. The lung abscess cavity will typically create an acute angle with the adjacent pleura whereas an empyema will form an obtuse angle with the pleura (Fig. 179.24). Additional similar cavitating lesions on CT would raise the differential diagnosis of septic emboli rather than lung abscess.

![FIGURE 179.24](image)

Axial CT of a 39-year-old nonsmoking female with cough and fever viewed on soft tissue (A) and lung (B) windows demonstrates a rounded intraparenchymal cavity with nodular mural thickening consistent with a lung abscess. The cavity resolved after 2 months of intravenous antibiotic therapy. CT, computed tomography.

**Empyema**

**Radiography.** By conventional radiography, visualization of the three-dimensional shape of the pleural lesion as oblong, flattened, and conforming to the shape of the thorax with an obtuse angle with the pleura helps differentiate between the two lesions. Abscesses are more rounded than empyemas and exhibit an acute angle with the pleural
Computed Tomography. Contrast-enhanced CT can be considered for adequate localization because there is a difference between the appropriate methods of treatment. The most reliable CT features for the differential diagnosis of lung abscess and empyema are wall characteristics, pleural separation, and lung compression. A lung abscess typically has a thick nodular wall and does not compress the adjacent lung. An empyema is surrounded by two enhancing pleural layers (split pleura sign) and compresses the adjacent lung (Fig. 179.25) [38].

![Empyema. Axial (A) and coronal (B) CT images of a 73-year-old female with a left staghorn calculus complicated by pyonephrosis and left empyema. The axial CT images exhibit enhancement of both layers of pleura (split pleura sign). The pleural collection has decompressed onto the chest wall (empyema necessitans). The empyema was successfully managed with intravenous antibiotics and pleural drainage. CT, computed tomography.](image)

Postpneumonectomy Space and Bronchopleural Fistula

After a pulmonary resection, air is seen in the pleural space from small air leaks in the cut surface of the lung. Small amounts of fluid also may be present. Air is usually reabsorbed gradually and continuously, followed by reabsorption of fluid, and both may be completely gone within the first 24 to 48 hours. Prolonged persistence of air and fluid may require drainage. Residual spaces may remain indefinitely without untoward effects and do not necessarily suggest bronchopleural fistula.

Air and fluid are always apparent in the hemithorax after a pneumonectomy and may be loculated in some cases. The normal
evolution is that of resorption of air and replacement by fluid. The rate of air resorption is variable, but the space left by a pneumonectomy is usually completely obliterated with fluid within 2 months [37]. If the quantity of air increases rather than decreases, one must consider the presence of a bronchopleural fistula.

**Radiography**

Failure of the postpneumonectomy space to fill; persistent or progressive pneumothorax despite chest tube placement; progressive subcutaneous or mediastinal emphysema; a 2-cm increase in the lucent component of the hydropneumothorax, with a shift of the mediastinum to the side opposite the postpneumonectomy space (Fig. 179.23); consolidation in the remaining lung because of transbronchial spillage; and a sudden pneumothorax or reappearance of air in a previously opaque postpneumonectomy space are predictive of bronchopleural fistula. A bronchopleural fistula can occur any time during the postoperative period but more often occurs within 8 to 12 days after surgery. If seen within the first 4 postoperative days, it is probably secondary to a mechanical failure of closure of the stump and requires reexploration and reclosure. A bronchopleural fistula also may occur after a supplicative pneumonia or massive pulmonary infarction, or even spontaneously. Empyema may occur alone or may be associated with a bronchopleural fistula. On the other hand, a bronchopleural fistula can occur without associated empyema, and the fluid in the pleural space in these cases is sterile. Several methods have been used to diagnose bronchopleural fistulas, including the instillation of methylene blue into the pleural space [39].

**Computed Tomography**

If bronchopleural fistula is suspected, increasing pneumothorax, hydropneumothorax, or mediastinal shift may be evident. CT is more sensitive than bronchoscopy for the direct imaging of bronchopleural fistula. Bronchopleural fistula can be confirmed if an airway is shown to communicate with gas in the pleural space [40].
CARDIAC ABNORMALITIES

Pericardial Effusion, Hemopericardium, and Tamponade

Radiography

Fluid or blood in the pericardial cavity is suspected when there is enlargement of the cardiac silhouette. The two layers of the normal pericardium are often seen as a pencil-thin line on the lateral chest radiograph. The normal pericardium is often seen anterior to the heart, separated from it by abundant epicardial fat. A line wider than 2 mm is diagnostic of pericardial fluid or thickening (Fig. 179.26). The epicardial fat sign on the lateral radiograph is thought to be the most sensitive radiographic sign of pericardial effusion [41,42]. Other described radiographic signs of pericardial effusion include a symmetrically enlarged “water bottle” cardiac silhouette and widening of the tracheal bifurcation angle [43]. CT and ultrasound remain the definitive tools for the diagnosis of pericardial effusion; ultrasound possesses the advantages of avoiding ionizing radiation and can be performed at the bedside.
FIGURE 179.26 Pericardial effusion. Chest radiographs and coronal and sagittal CT images of a 51-year-old patient with tuberculous pericarditis and dyspnea. Anteroposterior and lateral radiographs (A,B) demonstrate enlargement of the cardiac silhouette and a 2-cm rim of increased density surrounding the epicardial fat on the lateral radiograph (arrow, the epicardial fat sign). Coronal (C) and true short axis (D) contrast-enhanced CT reconstructions confirm the presence of a large circumferential pericardial effusion. CT, computed tomography.
Vascular Trauma

The initial diagnosis of injury to the thoracic aorta and the brachiocephalic arteries may be suspected on the basis of clinical signs. Laceration of the aorta and brachiocephalic vessels most frequently follows rapid deceleration with vehicular accidents or falls. The differences in the degree of fixation of the different segments of the aorta may cause sufficient stresses between segments in forceful deceleration to cause closed rupture. Flexion stress and a sudden increase in intraluminal pressure also may be the cause of injury. Blunt injury to the aorta typically occurs at the isthmus, between the origin of the left subclavian artery and the attachment of the ductus arteriosus [44]. The vascular injury is almost always transverse and may involve only one or all layers. When all layers are involved, exsanguination occurs; if the tear is only through the intima or the intima and media, the adventitia and the mediastinal pleura can contain the blood temporarily. If the diagnosis is missed, up to 90% of those who survive the initial impact will die within 4 months [45]. Therefore, the diagnosis must be very aggressively pursued.

Radiography

The presence of fractures of the first and second ribs suggests the possibility of associated vascular injuries. Confirmation by cross-sectional imaging is recommended, regardless of a normal radiologic appearance on plain radiographs, if the mechanism of injury could potentially affect the thoracic aorta and brachiocephalic vessels.

In an adequately penetrated radiograph of the chest, mediastinal widening appears to be the most useful sign suggesting a mediastinal hematoma (Fig. 179.27). A normal aortic outline without mediastinal widening makes the diagnosis of aortic or brachiocephalic vessel injury unlikely. A large meta-analysis reports that 92.7% of patients with traumatic aortic rupture have an abnormal mediastinum on initial radiography [39]. Described mediastinal abnormalities include a widened mediastinum, an abnormal aortic outline, opacification of the aortopulmonary window, downward displacement of the left mainstem bronchus, deviation of trachea to the right of midline, deviation of nasogastric tube to the right of midline, and a widened right paratracheal
Computed Tomography

Aortic and brachiocephalic injuries should be confirmed with cross-sectional imaging. Magnetic resonance imaging (MRI), transesophageal color-flow Doppler echocardiography, contrast-enhanced CT, and aortography all have high sensitivities (see Chapter 36 for a complete discussion of the circumstances under which each method is preferred). Direct signs of aortic injury on CT include an intramural hematoma (Fig. 179.28) or an aortic dissection (Fig. 179.27). Intramural hematoma is radiologically defined as crescentic thickening of the vessel wall in the absence of an intimal flap or entry tear, resulting from a hemorrhage within the aortic wall [47], it is often of higher CT density relative to unopacified blood on a noncontrast CT. Aortic dissection is defined as disruption of the media layer of the aorta with bleeding within and along the wall of the aorta caused by a tear in the intima of the aortic wall leading to the radiologic appearance of an intimal flap and false lumen (Fig. 179.27B). Indirect radiologic signs include periaortic hematoma, hemothorax, an increase in aortic caliber, and an irregular aortic luminal contour [48]. Associated rib fractures are common, seen in 75% of patients in one autopsy series [49].
FIGURE 179.28 A, B: CT of intramural hematoma.
Axial CT of a 79-year-old female who presented with acute chest pain. Crescentic thickening of the aortic wall from the origin of the right coronary artery to the aortic arch (arrows) in the absence of an intimal flap or a tear characterizes a type I intramural hematoma. CT, computed tomography.

Pulmonary Contusion, Hematoma, and Traumatic Lung Cyst

Radiography

Pulmonary contusion is a frequent cause of posttraumatic pulmonary opacification (Fig. 179.29). Radiologically, it manifests as increased density and/or consolidation with poorly defined margins that do not conform to the shape of the lobes or lung segments. The lack of sharp demarcation of consolidation is because of intra-alveolar blood or fluid. Increased density and consolidation usually manifest within the first 6 hours. Improvement of the lesion is rapid, occurring within 24 to 48 hours. Complete clearing is usually seen in 3 to 10 days. When laceration of a lung occurs as a result of a penetrating injury or surgical resection, a pulmonary hematoma form. The cavity formed by retraction of the torn elastic tissues may be completely dense or partially air filled if bronchial communication occurs. The lesion may progressively increase in size in the next few days because of edema or hemorrhage which both manifest as ground glass opacity. This is in contrast to a contusion, which typically decreases in size. The lesion may take weeks or months to clear. Resolution may be incomplete, resulting in a pulmonary nodule.

Computed Tomography
These findings and their complications are better characterized by CT. Pulmonary contusion manifests as ground glass opacity and consolidation when severe (Fig. 179.29). The abnormalities do not respect bronchopulmonary segmental anatomy. Subpleural sparing may be seen [50]. Pulmonary laceration manifests as rounded opacity rather than a linear opacity as is seen in other organs [50]. The laceration can also become air filled, giving rise to an air-fluid level. Secondary infection leads to liquefaction of dead tissues and bronchial communication, producing an air-filled cavity with or without an associated fluid level.

Lung cysts also may occur after trauma. They may appear immediately after blunt trauma or may form after several hours or days. Single, multiple, or multilocular thin-walled, oval to spheric cystic spaces may be seen in the lung periphery or subpleurally. Bleeding into the cyst from ruptured capillaries may occur. The lung cysts persist for long periods, often more than 4 months, but progressively decrease in size during this period (Fig. 179.29).

**Traumatic Diaphragmatic Hernia**

Severe diaphragmatic injury after blunt or penetrating trauma to the thoracoabdominal area may allow escape of abdominal contents into the thorax. The presence of a gas-containing viscus within the thoracic cavity is the hallmark of traumatic diaphragmatic rupture with an associated hernia. Most hernias occur on the left side, because the liver acts as a buffer on the right. Very often, the condition may be initially overlooked. Coexistent radiographic abnormalities such as atelectasis and pleural effusion may obscure the radiographic signs of herniation, and positive
pressure ventilatory support may delay herniation of abdominal contents through a ruptured diaphragm [51]. Symptomatic patients may experience intermittent incarceration of the herniated viscus.

**Radiography**

Findings suggestive of diaphragmatic rupture include a distorted elevated diaphragmatic outline, mediastinal shift, intrathoracic herniation of a hollow viscus (stomach, colon, small bowel), and visualization of a nasogastric tube above the diaphragm on the left side (Fig. 179.30) [52].

![Coronal CT images of two patients with traumatic diaphragmatic injury](image)

**FIGURE 179.30** Coronal CT images of two patients with traumatic diaphragmatic injury; features include discontinuity of the diaphragm (A, arrow), intrathoracic herniation of abdominal contents, and constriction of the herniating hollow viscus at the site of the diaphragmatic tear known as the collar sign (B, arrowheads). CT, computed tomography.

**Computed Tomography**

The CT features include discontinuity of the diaphragm (Fig. 179.30A), intrathoracic herniation of abdominal contents, a constriction of the herniating hollow viscus at the site of the diaphragmatic tear (known as the collar sign, Fig. 179.30B), and posterior displacement of the herniated viscera in the thorax (dependent viscera sign) confirming the absence of diaphragmatic support [52].

**Extra-Alveolar Air and Signs of Barotrauma**

**Pneumothorax**

**Radiography.** The diagnosis of pneumothorax is made when air is seen
superior, inferior, lateral, or anterior to the lung, and the visceral pleural line is identified. The air creates a zone of radiolucency devoid of lung markings between the lung and the thoracic wall. The lung partially (Fig. 179.31A) or more completely (Fig. 179.31B) collapses and drops to the most dependent position, slung by its fixed attachment at the pulmonary ligament.

**FIGURE 179.31** Frontal chest radiographs demonstrate small (A) and large (B) pneumothoraces after lung biopsy as evidenced by vertical pleural lines in the right hemithoraces (arrows).

As air accumulates in the pleura, the mediastinum tends to shift to the opposite side. This is best seen in a film taken during the expiratory phase of respiration. For the mediastinum to shift, the intrapleural pressure need only become less negative, not necessarily positive, on the side of the pneumothorax. Diminished negative pressure on the side of the pneumothorax creates sufficient imbalance between the pleural pressures of the two sides to cause mediastinal displacement during the expiratory phase of respiration. Tension pneumothorax causes a shift of the mediastinum to the opposite side during inspiratory and expiratory phases of respiration. In addition, diaphragmatic flattening, with progression to reversal of its normal curve, occurs in tension pneumothorax. The percentage of pneumothorax present in upright PA and lateral radiograph can be calculated by means of an average interpleural distance, using the total lung volume of the partially collapsed lung and the total hemithoracic volume as parameters [53]. Pneumothorax size can be predicted using a nomogram based on average interpleural distance.

The distribution of air in the pleural cavity is affected by pleural
adhesions and by disease of the underlying lung. Adhesions prevent lung retraction; therefore, extensive adhesions may lead to a loculated pneumothorax. A diseased lung, especially one with scarring or atelectasis secondary to bronchial obstruction, tends to retract to a greater degree than the adjacent lung. Obstructive emphysema, consolidation, and interstitial emphysema make the lung rigid and interfere with retraction, keeping the lung or the involved segment expanded. The distribution of air is also influenced by patient position because air rises to the nondependent portion of the thorax.

Early recognition of a pneumothorax is mandatory for ICU patients because of the risk of barotrauma or rapid progression to tension pneumothorax in an intubated patient. For the supine patient, air collects in the anterior portion of the thorax, between the medial portion of the lung and the anterior mediastinum, or in the subpulmonic area.

Subpulmonic pneumothorax is seen as a lucent area outlining the anterior costophrenic sulcus projected over the right or left upper quadrant or only as a deep lateral costophrenic sulcus on the involved side ([Fig. 179.32][54,55]). Flattening of the cardiac border or a lateral depression of the hemidiaphragm are additional signs of tension pneumothorax that should be sought in a supine patient with suspected pneumothorax if a pleural gas collection is not immediately apparent.

**FIGURE 179.32** Deep sulcus sign. Frontal supine chest radiograph in a 25-year-old male involved in a motor vehicle accident. The radiograph (A) and CT (B) demonstrate lucency outlining the anterior and lateral costophrenic sulcus projected indicating accumulation of air in the nondependent portion of the thorax. CT, computed tomography.

**Computed Tomography.** CT is not typically required to identify a pneumothorax, unless percutaneous drainage is intended, and CT is used for pre- and intraprocedural guidance.
Pulmonary Interstitial Emphysema

Pulmonary interstitial emphysema (PIE) occurs when air dissects through alveolar walls into the adjacent interstitial tissues where it forms cystic spaces and in adults and is typically associated with a medical intervention such as ventilation or biopsy. As a result, air dissects along the interstitium of the lungs, into the perivascular connective tissues, the interlobular septa, and the subpleural connective tissue, most extensively around the pulmonary veins [56].

Radiography. Radiologically, these spaces are seen as irregular radiolucent mottling in the medial one-half to two-thirds of the lungs or as discrete areas of radiolucency (Fig. 179.22). Radiolucencies are 2 cm or more in diameter and are best seen at the lung bases. PIE also may appear as radiolucent streaks radiating toward the hila or as a lucent halo around vessels on end. Subpleural blebs may be present most frequently around the hilar areas.

Interstitial emphysema changes rapidly, decreasing in size and disappearing completely in a matter of days. Differentiation of interstitial emphysema from necrotizing bronchopneumonia is sometimes difficult or impossible. Extensive PIE makes the lung appear better aerated than it actually is. PIE may progress to pneumothorax; infradiaphragmatic dissection; or mediastinal, cervical, or subcutaneous emphysema [57].

Computed Tomography. CT is not part of the routine investigation of PIE. When seen on CT, it manifests as cystic air spaces in the lung parenchyma, typically in a perivascular location and is typically accompanied by pneumothorax and pneumomediastinum (Fig. 179.22).

Subcutaneous Emphysema

Radiography. Air in the subcutaneous tissues is seen as linear streaks of lucency outlining tissue planes or as bubbles of lucency within the soft tissues (Fig. 179.33). Localized subcutaneous emphysema usually follows thoracostomy tube insertion, tracheostomy placement, and is usually of no significance. It may also be the earliest sign of pulmonary barotrauma. Extensive air in the subcutaneous tissues may occur in patients on ventilators, those with malfunctioning chest tubes, or those with bronchopleural fistulas. CT is not necessary to confirm subcutaneous emphysema but is usually incidentally noted when air has collected in other spaces such as the pleura or mediastinum (Fig. 179.33).
Pneumomediastinum

**Radiography.** Pneumomediastinum is manifested radiologically as vertical streaks of lucency just lateral to the borders of the heart, with the parietal and visceral pleura reflected by the lucent stripe (Fig. 179.33). When air extends into the soft tissues of the neck or into the retroperitoneum, it is most likely secondary to a pneumomediastinum.

**Computed Tomography.** Air can enter the mediastinum from a ruptured bronchus, trachea, or esophagus; from the neck (especially during the course of tracheostomy or line placement, when the negative pressure of the thorax draws air in through the incision). The site of rupture may be better characterized with CT.

Pneumopericardium

**Radiography.** Radiologic diagnosis of a pneumopericardium is made when a lucent stripe is seen around the heart extending to, but not beyond, the proximal pulmonary artery and outlining a thickened pericardium (Fig. 179.34). It may be difficult to differentiate from a pneumothorax or pneumomediastinum. Pneumopericardium is almost
always the result of surgery but also may follow trauma or infection.

**FIGURE 179.34** A: Chest radiograph in a 56-year-old male with duodenal perforation after esophagoduodenoscopy. Air in the pericardial space (arrowheads) is represented by curvilinear lucency which lies medial to the left ventricular free wall pericardium. B: Axial CT confirms extensive pneumopericardium, pneumomediastinum, and bilateral pneumothoraces which have tracked superiorly from the retroperitoneum. CT, computed tomography.

**Computed Tomography.** CT is more sensitive than radiography at detecting small quantities of pericardial air and may also be used to differentiate pneumopericardium from pneumomediastinum.
PULMONARY THROMBOEMBOLISM AND INFARCTION

Episodes of pulmonary thromboembolism usually show some changes on plain chest radiographs, such as linear atelectasis, elevation of a hemidiaphragm, or pleural effusion [58]. Most embolic occlusions occur in the lower lobes, the right more often than the left, probably as a result of hemodynamic flow patterns (see Chapter 92).

Radiography

Although pulmonary embolism is not typically perceptible on chest radiography, pulmonary oligemia, pulmonary infarction, and cor pulmonale can have radiographic manifestations. An area of increased radiolucency (local oligemia) of the lung within the distribution of the occluded artery is referred to as Westermark’s sign [59]. Pulmonary infarction manifests as parenchymal consolidation owing to tissue necrosis or hemorrhage and edema. The consolidation is almost always subpleural with a rounded medial edge (Hampton’s hump) (Fig. 179.35A). Infarcts vary in size, but most are 3 to 5 cm in diameter. Air bronchograms are rarely present; cavitation is unusual and, if present, suggests septic embolization. If infarction leads to necrosis, resolution averages 20 days and may take as long as 5 weeks. Cor pulmonale manifests as right ventricular cardiac enlargement, main pulmonary artery enlargement, increased size of the major hilar vessels with sudden tapering of the vessels, and dilatation of the azygos vein and superior vena cava are seen. These changes occur with massive or submassive pulmonary embolism. Pleural effusion is at least as common as parenchymal consolidation; the amount of fluid is frequently small, and the fluid is often unilateral.

**Figure 179.35** Chest radiograph and CT
Computed Tomography

The frequent presence of underlying chest disorders, such as ARDS, pulmonary edema, associated pneumonia, or chronic obstructive lung changes, often makes the radiologic diagnosis of pulmonary embolism virtually impossible on plain chest radiographs in the ICU patient. Radioisotopic scanning and CT provide superior sensitivity for pulmonary embolism. CT scanning is typically preferred in the acutely ill patient because it is more reliable in the setting of chronic obstructive pulmonary disease, requires a shorter imaging time, and can indicate alternative diagnoses, if negative for pulmonary embolism. The direct CT signs of pulmonary embolism include:

1. An intravascular filling defect(s) that either partially or completely occludes the vessel. Acute pulmonary emboli are typically centrally located in the vessel and may produce dilatation of the affected vessel (Fig. 179.36). In the case of chronic pulmonary embolism, the filling defect may either be curvilinear or weblike and lies within peripheral pulmonary arteries, often at arterial branch points. Pulmonary arterial occlusion is typically absent owing to recanalization.

2. Indirect CT signs of pulmonary embolism include peripheral wedge-shaped or rounded areas of hyperattenuation (pulmonary infarction) (Fig. 179.35) or linear parenchymal bands in the subpleural lung. In the case of large pulmonary emboli or chronic pulmonary embolism, features of right heart strain should be sought, including right ventricular dilatation, contrast material reflux into the hepatic veins, and deviation or straightening of the interventricular septum toward the left ventricle (Fig. 179.37) [60].
**FIGURE 179.36** CT pulmonary angiogram in a 41-year-old male with colorectal carcinoma and dyspnea. Axial (A) and coronal (B) CT images confirm bilateral intravascular filling defects which complete or partially occlude the pulmonary arteries (arrows). CT, computed tomography.

**FIGURE 179.37** Axial (A) and true cardiac short axis (B) images of a gated CT pulmonary angiogram in a patient with long-standing pulmonary hypertension. The right ventricle is moderately dilated, and the interventricular septum is straightened toward the left ventricle (arrows) (rather than the normal configuration of bowing toward the right ventricle) consistent with raised right ventricular pressures. CT, computed tomography.
EXTRAPULMONARY STRUCTURES

Evaluation of the chest radiograph is never complete unless the extrapulmonary, extrapleural, and extracardiac structures (extrathoracic soft tissues and bones of the thorax) are carefully assessed for possible pathology. It is not the purpose of this chapter to deal with these pathologic processes in depth; suffice it to say that one should look for masses, calcifications, and abnormal air collections such as abscesses in the cervical and thoracic soft tissues and subphrenic areas. The osseous structures also may provide clues to disease of a systemic nature (e.g., H-shaped vertebrae and bone infarcts in sickle cell anemia) or to metastases in the form of lytic or blastic bone lesions. Fractures after trauma, and occasionally rib fractures from resuscitation procedures after cardiac arrest, may be seen on the chest radiograph.

Severe Upper Airway Infections
SUMERA R. AHMAD • STEPHEN J. KRINZMAN
• SUNIL RAJAN • RICHARD S. IRWIN

The components of the upper airway include the nose, mouth, nasopharynx, oropharynx, and hypopharynx. It communicates with the paranasal sinuses and tympanic cavities. Although minor infections of these areas are commonly observed in the outpatient setting, occasionally, they may become severe and life threatening. This class of disease requires intense observation and aggressive management and is the focus of this chapter.

SINUSITIS

For patients on mechanical ventilatory support, sinusitis is one of four common causes of fever, along with pneumonia, catheter-related infection, and urinary tract infection [1–4]. Sinusitis is encountered in the intensive care unit (ICU) in two situations: as an uncommon, potentially fatal complication of a community-acquired sinus infection such as meningitis, osteomyelitis, orbital infection, or brain abscess and as a hospital-acquired sinus infection that may be a frequent cause of occult fever for a critically ill patient.

Incidence

The frequency of radiographically documented sinusitis among mechanically ventilated patients varies greatly from 18% to 88%, with a mean of 56% in one recent meta-analysis [5]. Of note, 67% of the patients reviewed were nasally intubated. Using criteria to identify patients with clinical evidence of sinus infection—fever; leukocytosis or leukopenia;
and purulent sinus secretions—clinical sinus infection was present in one half of patients with radiographically demonstrated sinusitis [5]. In one series, 95% of nasotracheally intubated patients developed radiographic evidence of pansinusitis [6], as did 25% of patients who were orotracheally intubated.

Pathogenesis

Critically ill patients are predisposed to develop nosocomial sinusitis for several reasons. The diameter of the ostia, normally as small as 1 or 2 mm, has been shown to decrease with recumbency as much as 23% because of venous hydrostatic pressures [7]. In addition, the maxillary sinus ostia are poorly located for gravitational drainage [7]. Nasotracheal and nasogastric tubes strongly predispose patients to develop radiographic changes of sinusitis (OR 4.66 for nasally vs. orally intubated patients), and in one series, 73% of mechanically ventilated patients developed culture-proven sinusitis within 7 days of placement of nasogastric or nasotracheal tubes [6]. Larger intranasal tubes (tracheal) induce radiographic sinus changes more quickly than smaller tubes (gastric) [4]. Using multiple logistic regression analysis, risk factors for nosocomial sinusitis, of strongest association, are sedative use; nasogastric feeding tubes; Glasgow coma scale less than 8; and nasal colonization with enteric gram-negative bacteria [8].

Etiology

The microbiology of nosocomial sinusitis is quite distinct from that of community-acquired sinusitis, and is similar to that of other nosocomial respiratory infections. Nosocomial sinusitis is polymicrobial in 54% of cases, with gram-negative aerobic organisms being the most common causative agents (49%), followed by gram-positive aerobic organisms (37%), fungi (7.5%) and anaerobes (7.5%). The most commonly isolated pathogens are Streptococcus spp. including Streptococcus pneumonia (13%); Pseudomonas spp. (13%); Staphylococcus aureus (11%); E. coli (9%); coagulase negative staphylococci (6%); Acinetobacter spp. (5%); and Klebsiella spp. (5%) [5]. The organisms isolated in nosocomial sinusitis are the ones frequently identical to those cultured from the lower respiratory tract [3,9]. Such findings support the concept of general colonization of the airway mucosa of critically ill patients.

Specific situations warrant consideration of infection with more unusual pathogens. Acute invasive fungal rhinosinusitis (AIFR) is a rare condition, but has a mortality rate of 40% to 50% [10]. Affected patients are usually immunocompromised, with the most common comorbidities being hematologic malignancy, diabetes, medical immunosuppression, renal failure, and HIV. Aspergillus and species of Zygomycetes such as
Mucor are identified in the majority of cases, with Mucor spp. being more commonly found in diabetic patients, and Aspergillus spp. being found in patients with severe HIV-associated immunosuppression or hematologic malignancies. The most common presenting symptoms are fever, purulent nasal drainage, facial pain, facial swelling, nasal crusting, and visual symptoms [10]. Common nasal endoscopic findings include necrotic mucosa and hyaline or thick mucus secretion. Radiographically, sinus opacity and bony erosion are seen in all cases, and these findings are usually unilateral [11]. Treatment consists of surgical debridement and systemic antifungal therapy. *Cryptococcus neoformans* can cause sinusitis with a high relapse rate and significant mortality in immunocompetent and immunocompromised patients [12]. *Candida* spp. [13]; *Pseudoallescheria boydii* and *Cytomegalovirus* spp.; and other unusual organisms have been isolated in patients with acquired immunodeficiency syndrome with sinusitis [14].

**Complications**

Complications of acute sinusitis are rare but can be rapidly fatal and are best managed in an ICU. Orbital complications include edema, predominantly of the eyelids, orbital cellulitis, orbital abscess, subperiosteal abscess, and cavernous sinus thrombosis [15,16]. The last one is the most severe, with a mortality of greater than 20% [17–19]. Intracranial complications have an overall mortality of 40% and include osteomyelitis, meningitis, epidural abscess, subdural empyema, and brain abscesses [17–19]. For these cases, sinus drainage is imperative and antibiotics are started early and redirected by culture results.

Several investigators have examined the relationship between nosocomial sinusitis and ventilator-associated pneumonia. In adult, intubated patients with clinically evident sinusitis, ventilator-associated pneumonia (VAP) is also present in 41%, and the incidence of VAP is higher among patients with sinusitis than for those without. The same organism can be isolated from both the lung and sinuses among 59% of such patients. In addition, clinically evident sinusitis increases the risk of bloodstream infections, and in patients with sinusitis and bloodstream infections, the same organism is identified among 20% of cases [5]. A prospective, randomized study of a strategy to systematically detect and treat nosocomial sinusitis, both radiographic evidence and bacteriologic evidence of sinusitis were reported for 55% of febrile, mechanically ventilated patients [20]. All patients in the study were nasotracheally intubated. Seventy percent of patients with positive radiographs had positive quantitative cultures. VAP occurred for significantly fewer patients (34% vs. 47%, *p* = 0.02) of the group for which there was systematic screening for and treatment of sinusitis. Taken together, these
findings suggest a causal relationship between nosocomial sinusitis and VAP.

Nosocomial sinusitis may also cause fever of unknown origin (FUO) in mechanically ventilated patients. van Zanten and colleagues prospectively studied 351 orotracheally intubated patients with fever for more than 48 hours despite treatment with broad-spectrum antibiotics [3]. In 198 patients, the cause of the fever remained unknown despite initial investigations that included chest radiographs. Based on the results of sinus radiographs and subsequent sinus cultures, infectious sinusitis was confirmed for 30% of patients with FUO and was found to be the sole cause of fever for 16% of cases.

**Diagnosis**

**Computed Tomography Scans and Radiographs**

Computed tomography (CT) scanning has become the imaging modality of choice for the diagnosis of nosocomial sinusitis. Compared with plan sinus radiographs, sinus CT scans can more accurately visualize the ethmoid and sphenoid sinuses and are also superior in differentiating mucosal thickening from air–fluid levels [21]. Portable sinus radiographs performed in the supine position have been recommended to identify sinus infections among critically ill patients who cannot travel for standard sinus films or a CT scan [22]. As discussed earlier, patients may have sterile cultures despite radiographic evidence of sinusitis.

**Ultrasonography**

With the increasing use of ultrasound in the ICU, there has been a renewed interest in this modality to diagnose nosocomial sinusitis. Although bone often presents obstacles to ultrasound imaging, the anterior walls of the maxillary sinuses are flat bones composed of compact tissue, allowing adequate ultrasound penetration. Prior investigations had demonstrated that ultrasound was 67% sensitive and 87% specific for maxillary sinusitis visualized on CT scans [23]. Accuracy is improved when the patient is in the semi-recumbent position, rather than supine [24].

More recent investigations have shown further improvements of diagnostic accuracy. Vargas and coworkers used B-mode ultrasound in
the semi-recumbent position in 120 patients with suspected sinusitis [24]. They found that among 36 patients with negative sinus ultrasounds, none had evidence of maxillary sinusitis on CT scan. Extensive maxillary sinus disease is indicated by hyperechogenic visualization of the posterior wall and extension to the internal and external walls was, in one investigation, found to be 100% specific for total opacification of the sinus on CT scan [25]. On transnasal puncture, fluid could be aspirated from all such patients, and the cultures were positive for 67% of patients [24]. In patients where only the posterior wall of the maxillary sinus is hyperechogenic, 80% of transnasal punctures yield fluid, and cultures are positive in half of those where fluid is obtained.

**Rhinoscopy and Antral Aspiration**

As reviewed earlier, opacification of the paranasal sinuses among the critically ill patient does not necessarily indicate infectious sinusitis; in some series, half or more of such patients have sterile cultures. Rhinoscopy can add significantly to the diagnostic yield for patients with suspected sinusitis. In patients with both purulent secretions in the middle meatus by rhinoscopy and radiographic evidence of sinusitis, 92% have positive cultures by antral lavage. Although cultures obtained from the maxillary sinus by antral puncture had previously been considered the gold standard for diagnosis of nosocomial sinusitis, endoscopically guided middle meatal cultures accurately reflect cultures obtained from direct maxillary sinus aspiration in 85% to 100% of patients [26]. Bilateral cultures should be obtained, as in one series, two-thirds of the positive cultures were negative on the contralateral side [26].

**Treatment**

Nosocomial sinusitis is most often related to the presence of nasopharyngeal and oropharyngeal catheters and tubes [4,27,28]. Therefore, in addition to antibiotics and decongestants, treatment includes removal of all nasal tubes to eliminate the source of obstruction and irritation in addition to decongestants and antibiotics. Because the spectrum of bacteria causing nosocomial sinusitis is similar to that causing other nosocomial respiratory infections [4,29,30], broad-spectrum gram-positive and gram-negative coverage is indicated. With removal of nasal tubes and antibiotic therapy, 67% of patients become afebrile within 48 hours [31]. The optimal treatment for nosocomial sinusitis remains uncertain and antibiotic selection should take local antibiograms into account. In a prospective randomized trial demonstrating clinic improvement when sinusitis was systematically investigated and treated, the treatment consisted of endoscopic
transnasal puncture for culture, broad spectrum antibiotics, and serial catheter directed sinus lavage [20]. To our knowledge, no study has randomized patients to medical versus surgical treatment.
SPHENOID SINUSITIS

Sphenoid sinusitis deserves separate mention because of its potentially fulminant nature and difficulty of diagnosis. Delay in its diagnosis has been associated with serious morbidity and mortality [32,33]. The typical presentation of acute infection is severe headache that interferes with sleep, often accompanied by fever and nasal discharge [32,33]. Neurologic deficits can be prominent features; trigeminal hyperesthesia or hypoesthesia occurs in one third of cases [33]. Gram-positive organisms have been isolated from the cultures of most patients with acute sinusitis, whereas equal numbers of gram-positive and facultative gram-negative pathogens have been cultured from those with chronic sphenoid sinusitis [32,33]. Serious sequelae including permanent neurologic deficits and death can result from the spread to nearby structures (e.g., cavernous sinus, pituitary gland, optic chiasm). When findings suggest extension of the infection, early CT scan of the sinuses is essential. Surgical drainage may be necessary if symptoms persist or neurologic signs develop while the patient is receiving appropriate antibiotic therapy.
OTOGENIC INFECTIONS

Serious complications of otologic infection occur rarely [34,35]. Anatomically, the external auditory canal is one-half cartilaginous, and the medial half tunnels through the temporal bone. The auditory tubes (pharyngotympanic tube) pass into the nasopharynx along the superior border of the lateral pharyngeal spaces (LPS). Other structures that are accessible to pathogens include the mastoid air cells, the jugular foramen, cranial nerves (especially the facial nerve), the internal carotid artery, and the dura mater of the posterior cranial fossa.

Mastoiditis

Acute mastoiditis is an uncommon complication of otitis media, seen primarily in children and young adults. Inflammation spreads from the middle ear to the modified respiratory mucosa lining of the mastoid air cells, by direct invasion of the bone or through the mastoid emissary veins. The closed space infection leads to accumulation of purulent exudate, increased pressure, and bony necrosis. Pain, typically postauricular, fever, and abnormal tympanic membranes are the most common findings on presentation, and a fluctulent mass may be noted, causing anterior displacement of the auricle [36]. The duration of symptoms averages 10 days [36]. In a review of 202 hospitalized children, the most frequent culture result was “no growth” (30%), followed by Streptococcus pneumoniae (21%), skin flora (14%), Pseudomonas aeruginosa (7%), Streptococcus pyogenes (7%), and Staphylococcus aureus (4%) [37]. Radiographic abnormalities may be evident on CT or MRI imaging that can reveal opacification or cloudiness of the mastoid air cells and, less frequently, evidence of bone destruction [38]. Although uncommon (1.9%), complications can include conductive hearing loss, facial palsy, sinus thrombosis, subdural and epidural abscess, and meningitis [36,38]. Treatment includes broad-spectrum antibiotics that can adequately penetrate cerebrospinal fluid and surgical intervention for those who fail to improve within 24 to 72 hours.

Chronic mastoiditis and chronic otitis media result from a progressive inflammatory process that usually leads to obstruction of the communication between the middle ear and mastoid (aditus) or the middle ear and nasopharynx (eustachian tube) [39]. Often a
cholesteatoma or epidermal inclusion cyst within the tympanomastoid compartment may be involved and may become secondarily infected [39]. Presenting symptoms include hearing loss, painless otorrhea, and tympanic membrane perforation [39]. Other symptoms (e.g., facial nerve paresis, headache, ear pain, fever) may be present if complications have occurred. Uncomplicated chronic otitis media and mastoiditis are treated medically with local hygiene, topical antibiotics often including a corticosteroid, and oral, or infrequently parenteral, antibiotics [39]. Broad-spectrum antibiotics are required to cover a wide range of aerobic and anaerobic organisms. Surgery is usually reserved for recurrent disease, often associated with a cholesteatoma, which can be identified by CT scan of the temporal bone [39].

**Malignant External Otitis**

Malignant, or necrotizing, external otitis (MEO) most often affects elderly diabetic patients. Diabetic microangiopathy, impaired chemotaxis and phagocytosis, combined with the ability of *Pseudomonas aeruginosa* to invade vessel walls, causes vasculitis with thrombosis, leading to the characteristic pathophysiology of this of this disorder [40]. The majority of patients (65% to 100%) have diabetes mellitus, but MEO may also develop in patients with other forms of immunosuppression, including HIV/AIDS, hematologic malignancies, after chemotherapy and with solid organ transplantation [40,41]. MEO most commonly presents with otalgia, granulation tissue in the external auditory canal, most prominently at the osteocartilaginous junction, and often purulent and fetid otorrhea [42]. Spread of infection is anteriorly toward the parotid compartment or downward into the temporal bone; spread to the mastoid is less common [34]. Extension leads to pain and tenderness of the tissues around the ear. *P. aeruginosa* is the most commonly implicated pathogen (85%) [42]. Patients with acquired immunodeficiency syndrome may develop infection from a wider variety of organisms and may accumulate less granulation tissue in the external auditory canal [43]. *Aspergillus* spp. have been identified, primarily in immunocompromised patients [44,45]. Osteomyelitis [46], cranial nerve paralysis [47], and central nervous system (meningitis) and vascular (thrombophlebitis) spread [48] are potential severe and fatal complications of MEO.

CT and magnetic resonance imaging scanning, along with technetium-99 bone scans, are valuable components of the diagnostic evaluation of MEO [48]. CT scans may show erosion of the tympanic bone (80%), and clouding of the mastoid cells in 19.5% [41]. CT scans may be normal among 11% of cases [41]. Thus, if there is a high clinical suspicion, technetium-99 bone scans should be obtained, and are positive in close to
100% of cases [40]. Surgical interventions may not be required, but management does require biopsy and culture, and may require debridement and drainage of associated abscess [40]. Therapy for MEO includes prolonged antibiotics directed against *P. aeruginosa* unless the culture data suggest another pathogen. This may include a semisynthetic penicillin, ceftazidime, or oral fluoroquinolones [48]. The duration of treatment is not clearly defined and complete response is defined by resolution of signs and symptoms.
SUPRAGLOTTITIS (EPIGLOTTITIS)

Acute supraglottitis is an uncommon infection of the structures located above the glottis. These structures include the epiglottis, aryepiglottic folds, arytenoids, pharynx, uvula, and tongue base. The true vocal cords are rarely involved. The infection may progress to abrupt and fatal airway obstruction. This entity is well described in children, in whom the presentation and course are usually fulminant. In the pediatric population, increased awareness and prophylactic airway control have reduced overall mortality to less than 1% [49,50]. Although this disease at one time affected primarily children, with the introduction of the conjugate vaccine for Hemophilus influenza type b (Hib), there has been a dramatic decline in pediatric infections, and supraglottitis is becoming a disease of adults. In children, H. influenzae type B is still the most commonly identified causative organism.

Incidence

In the post–H. influenzae type B vaccine era, the annual incidence of acute supraglottitis is estimated between 0.6 and 0.78 cases per 100,000 immunized children [51]. Among adults, the incidence of acute supraglottitis has increased from 0.79 cases per 100,000 adults in 1986 to 2.1 cases per 100,000 adults in 2005 [52]. Adults with acute supraglottitis usually present in their 40s and 50s, with a male preponderance, and children usually present between the ages of 2 and 5 years [52].

Pathogenesis and Pathophysiology

Among children, the inflammation is mainly restricted to the epiglottis because of loose mucosa on its lingual aspect. This provides a readily available space for edema to collect within. Swelling reduces the airway aperture by curling the epiglottis posteriorly and inferiorly, accentuating the juvenile omega shape. When edema spreads to involve the aryepiglottic folds, respiratory distress can occur as inspiration draws these structures downward, further exacerbating the obstruction and resulting in stridor. The adult airway is relatively protected because the larynx is larger and the epiglottis is shaped more like a spatula.

Etiology

H. influenzae type B is the most common cause identified among
pediatric cases, even in the post-vaccine era [51,53]. In adults, numerous bacterial, viral, and fungal organisms have been implicated, including *Hemophilus influenza* type B, *Streptococcus pneumonia*, *Staphylococcus aureus*, *Streptococcus* spp., *Moraxella catarrhalis*, *Pseudomonas* spp., *methicillin-resistant Staphylococcus aureus* (MRSA), and *Neisseria* spp. Non-bacterial agents include *Candida albicans*, and viruses such as Herpes simplex, Parainfluenza, Varicella zoster, and Epstein-Barr. Among adults, blood cultures are positive in less than 20% of cases, and *H. influenzae* is the isolate for one-third of these cases [53,54].

Noninfectious causes of acute supraglottitis have been described and include thermal injuries related to inhalation drug use, ingestion of hot food, apparent caustic injury from aspiration, and posttransplant lymphoproliferative disorder [55,56]. McKinney and Grigg [57] described a case of epiglottitis after general anesthesia administered via a laryngeal mask.

**Diagnosis**

**History and Physical Examination**

For children, the classic presentation is of a 3-year-old child who initially complains of a sore throat followed by dysphagia and/or odynophagia, which then progresses within hours to stridor. The child prefers to sit, leaning forward, and usually appears pale and frightened. Breathing is slow and quiet with characteristic drooling noted. These symptoms may lead to sudden respiratory depression and arrest. The progression of symptoms can be remembered as the four “Ds”: dysphagia, dysphonia, drooling, and distress. Children with acute supraglottitis rarely present with coughing that may help to distinguish them from those with laryngotracheobronchitis or croup [51].

Among adults, the classic presentation is more the exception than the rule, and as such, the frequency of misdiagnosis has been reported as high as 60% to 75% [49,52]. More than 90% of adults seek medical attention complaining of sore throat with or without dysphagia [56,59]. Many patients report antecedent upper respiratory tract infections [59,60], and between 60 and 90% will have an elevated temperature [51]. Other less common signs and symptoms are respiratory distress, muffled voice, drooling, and stridor [49,50,53,55,58]. Hoarseness or true dysphonia is not observed because the process usually spares the true
vocal cords. Children and adults often prefer an upright posture with the neck extended and mouth slightly open [59].

The duration of symptoms varies, ranging from hours to several days [61]. Patients who present early in their disease course have more severe symptoms, fever, and leukocytosis, and those presenting within 8 hours of the onset of symptoms are more likely to have signs of upper airway obstruction [62]. They are also more likely to be infected with *H. influenzae* [61]. These patients are at increased risk of needing artificial airways and of dying [63].

Evaluation of patients with suspected supraglottitis depends, in part, on their age and the severity of their symptoms. For young children with a classical presentation, pharyngeal examination should not be attempted. An artificial airway should be established in the controlled setting of an operating room, where an examination can be performed with less risk of airway obstruction.

For older children and adults, supraglottitis should be considered when sore throat and dysphagia seem to be out of proportion to visible signs of pharyngitis. In this situation, if the patient has no respiratory distress, examination of the larynx and supralaryngeal structures is recommended. The epiglottis may appear cherry red in color but more commonly is pale and edematous. Other supraglottic structures may be edematous as well, resulting in the inability to visualize the vocal cords [51].

**Diagnostic Tests**

Although considered the classic radiographic finding, the “thumb sign,” indicating a swollen epiglottis (Fig. 180.1), may be negative in up to 56% of cases [51], so its absence should never be used to exclude the diagnosis. When there is significant clinical suspicion, direct visualization of the structures should be performed [64]. The radiograph should be taken in the upright position to avoid pooling of secretions posteriorly and potentially increasing the obstruction, and the patient must be observed at all times by someone skilled in airway management.
Acute supraglottitis. Lateral radiographs of the neck obtained with soft tissue technique in a 2-year-old child (A) and a 42-year-old adult (B). There is epiglottic (e) swelling (thumb sign), thickening of the aryepiglottic folds (a), and narrowing of the vallecula (arrow) in both patients. Compare with normal epiglottis in Figure 180.11(a).

Few laboratory tests are helpful at the time of initial evaluation. An elevated white blood cell count and C-reactive protein level may identify a patient at higher risk. Throat cultures are positive in less than 33% of the cases, and blood cultures detect a causative agent in less than 20% of the cases [52,55]. Swab culture of the epiglottis obtained under direct visualization may better reflect the causative agent, and has been positive in up to 75% of the cases [55,58].

Differential Diagnosis

Supraglottitis of children is a clinical diagnosis. Because immediate airway control is a priority, recognizing other pediatric illnesses presenting with a sore throat and not requiring this intervention is important [65,66]. The most common infection is croup, a predominantly viral laryngotracheobronchitis that occurs up to 40 times more frequently than epiglottitis [66]. Typically, the child is younger than 3 years and has had an upper respiratory tract infection of at least 48 hours’ duration.
Hoarseness develops initially and is followed by a distinctive barking cough. Although respiratory distress with stridor is common, intubation is rarely needed [65,66]. Anteroposterior and lateral views of the neck may show the classic, “steeple sign” (Fig. 180.2), a gradual narrowing of the proximal tracheal air column secondary to subglottic edema. Other less common infectious considerations for children include pseudomembranous croup (bacterial laryngotracheobronchitis), retropharyngeal abscess, lingual tonsillitis, and diphtheria [65,66].

![Croup Radiograph](image)

**FIGURE 180.2** Croup. Anteroposterior radiograph of the neck in a 19-month-old child. Subglottic edema produces smooth tapering (arrowheads) of the tracheal air column (the steeple sign).

Among adults, infectious mononucleosis, often with massive tonsillar hypertrophy leading to stridor, and a unilateral pharyngeal mass should be considered when patients complain of sore throat and dysphagia. Pharyngitis may present a picture indistinguishable from that of mild or
early supraglottitis [63].

Bacterial tracheitis is a potentially life-threatening illness with features similar to those of supraglottitis and viral croup. Although more often seen among the pediatric population, adults can also be affected [67]. These patients present with a brief, progressive upper respiratory tract prodrome including a brassy cough, stridor, high fever, and toxicity but do not exhibit dysphagia or drooling [65,66]. Airway obstruction is caused by subglottic mucosal edema and thick, inspissated, mucopurulent tracheal secretions [67]. Bacterial superinfection of a preceding viral tracheitis occurs most commonly with \( S. \) \( aureus \) and \( H. \) \( influenzae \) [66]. Rare cases of membranous tracheobronchitis due to a fungal agent have been described among immunocompromised hosts [60], but these infections have involved primarily the lower respiratory tract. Lateral neck radiographs demonstrate subglottic narrowing and may show mucosal irregularities or membranes in the tracheal air column [68]. Chest radiographs may show signs of atelectasis due to central bronchial obstruction by mucus or necrotic debris [69]. Management is similar to that for supraglottitis, and bronchoscopy should be performed for diagnosis [70]. Intubation or tracheostomy is usually necessary to relieve obstruction and provide adequate tracheal suctioning [67,70]. Antibiotic therapy should be directed against \( S. \) \( aureus \) and other common causative respiratory pathogens.

Rhinoscleroma should also be considered in the differential diagnosis. \( Klebsiella \) \( rhinoscleromatis \) is the etiologic agent of this chronic granulomatous disorder [71,72]. Although nasal and oral mucous membranes are the most common sites of infection, patients have presented acutely with upper airway obstruction due to indolent spread to the larynx and tracheobronchial tree. This condition may be seen in immigrants to the USA from endemic areas such as Central America, Central Europe, Africa, and Asia. The nodular and indurated endoscopic appearance is nondiagnostic, so multiple biopsy specimens for culture and histologic examination are required. Treatment is with a prolonged course of oral antibiotics. Repeated cultures of biopsy specimens may be needed to ascertain whether bacteriologic cure has been achieved [72].

Noninfectious causes of acute upper airway obstruction are usually suggested by the history obtained and by the patient’s nontoxic appearance. These include foreign body aspiration; allergic edema; chemical laryngitis from gastroesophageal reflux; and necrotizing tracheobronchitis as a complication of mechanical ventilation [73]. Paraquat poisoning can cause a pharyngeal membrane similar to diphtheria that is accompanied by signs of shock and sepsis [74].

**Treatment**
The treatment of supraglottitis has two major components: airway management and medical therapy. The early placement of an artificial airway for children has significantly reduced mortality. Moreover, because airway obstruction is the most common cause of death among adults for whom airways are not secured when the diagnosis of supraglottitis is made, some authors favor establishing an artificial airway prophylactically, as is performed in children [50,52,61]. In one series [75], adult patients who presented with stridor within 24 hours of onset of symptoms had a rapidly progressive course, requiring airway interventions, whereas those presenting with similar symptoms but with a longer interval since symptom onset responded to medical therapy. For these reasons, we favor reserving intubation for adult patients with early signs of airway obstruction [56,61,76], or those with recent onset and rapid progression of symptoms. All patients should be observed in an ICU with the immediate availability of equipment and personnel for emergent intubation.

Both tracheostomy and translaryngeal endotracheal intubation have been performed. No difference in mortality has been reported when comparing these two modalities [77,78]. Significant reductions for duration of airway control, incidence of upper airway complications, and length of hospital stay have been observed in patients with endotracheal intubation when compared with tracheostomy [78,79]. The acute complications of tracheostomy, including pneumothorax, hemorrhage, and subcutaneous or mediastinal emphysema, occur with increased frequency among patients younger than 12 years [77]. Accidental extubation, particularly for children, is the greatest risk of endotracheal intubation [77,78]. Much of the morbidity of the artificial airway is associated with its prolonged maintenance, which is unlikely to occur with supraglottitis. In one large series, 90% of children were extubated in less than 24 hours [80]. The choice of an artificial airway should be determined by the skill of available personnel in placing and maintaining the airway. Endotracheal intubation is preferred, with surgical backup, should the attempt fail.

The appropriate time for extubation in a patient recovering from acute supraglottitis varies. Some physicians remove the artificial airway when the patient’s general toxic appearance and fever have subsided [80]. Others wait until repeat laryngoscopy or lateral neck radiographs show decreased edema of the involved structures [81]. One can deflate the cuff of the endotracheal tube to test for an air leak around the tube or the patient’s ability to breathe with the tube plugged for a brief moment [82].
It is important to remember that if the tube fills the trachea, the patient may not be able to breathe even if supraglottitis has completely resolved. Medical therapy is crucial for rapid recovery from supraglottitis. All patients require close observation, humidification, and, often, mild sedation [53]. Many antibiotics are effective, and the regimens must cover *H. influenzae* infection. With the high frequency of β-lactamase–producing strains of *H. influenzae*, ampicillin is no longer adequate as an initial single agent. The initial drug of choice is a second- or third-generation cephalosporin that covers ampicillin-resistant *H. influenzae* as well as the other possible pathogens in adults: *S. aureus*, *S. pneumoniae*, and other streptococcal species [64]. Cefotaxime has been considered the antibiotic of choice; ceftriaxone and ampicillin/sulbactam have also been found to be effective [53]. Trimethoprim–sulfamethoxazole can be used as an alternative agent for penicillin-allergic patients. With the rising frequency of penicillin-resistance and multidrug-resistant *S. pneumoniae*, the initial antibiotic regimen may require modification based upon culture data. The antibiotics should be initially administered intravenously for several days, depending on the response, and then continued by mouth for 7 to 10 days [82].

Corticosteroid therapy is controversial for patients with infectious supraglottitis. Many authors, finding no contraindications, use steroids empirically [53,77]. There have been no randomized, controlled trials assessing the effectiveness of corticosteroids for patients with acute epiglottitis (Table 180.1). Steroids have been noted to be effective in a large, randomized, controlled trial of children with moderate-to-severe croup, lending some support to the hypothesis that steroids may be beneficial in infectious upper airway disease [83]. The use of a helium–oxygen mixture (Heliox) could be considered to diminish the work of breathing and provide a bridge to avoid intubation while antibiotics take effect.

<sup>a</sup>Cultured from epiglottic swab or seen on autopsy; all others recovered from blood.

<sup>b</sup>Epiglottis biopsy specimen histology and viral culture.

Complications of the disease differ between the pediatric and adult populations. The former has a higher incidence of pneumonia and accidental extubation [84]. Pulmonary edema immediately after intubation for severe stridor has been described among children [85]. For adults, an epiglottic abscess may be suggested by a persistent or deteriorating clinical condition [86,76]. CT scan of the neck may be helpful for making this diagnosis, particularly if direct visualization is not adequate [86,87]. Both groups face risks and complications associated with intubation and tracheostomy [79]. Treatment recommendations are outlined in Figure 180.3.

INFECTIONS OF THE DEEP SPACES OF THE NECK

Deep neck infections can be fatal extensions of upper airway infections. These potentially catastrophic infections are infrequently encountered today because of the prompt treatment of pharyngitis, tonsillitis, odontogenic, and otologic infections with antibiotics [88]. Deep neck infections are more common in males, smokers, alcoholics, and intravenous drug users [88]. They can be fatal for patients who are immunocompromised such those with HIV, diabetes mellitus, chronic steroid use and those undergoing chemotherapy [89]. In a retrospective analysis of 365 patients, the presence of diabetes mellitus and multiple deep neck space infections were the strongest predictors of complications [90]. Airway obstruction and mediastinitis were the most troublesome of complications [90], but patients may also develop jugular vein thrombosis, pneumonia, pericarditis, and arterial erosion [91]. Tonsillitis remains the most common cause of this disease in children, whereas poor dental hygiene and injection drug abuse are the most common causes in adults [91]. Other causes include trauma, surgical trauma, esophageal perforation, laryngopyocele, infected branchial cleft, infected thyroglossal duct cysts, thyroiditis, and mastoiditis with Bezold’s (mastoid tip) abscess [91]. An understanding of the complex interconnections between anatomic spaces is essential for early diagnosis and timely intervention of these conditions.

General Pathogenesis and Anatomy

Knowledge of the cervical fasciae is a prerequisite to understanding the etiology, manifestations, complications, and treatment of deep neck infections. The fascial planes separate and connect distant areas, thereby limiting and directing the spread of infection (Fig. 180.4). Suppurative processes in the submandibular, lateral pharyngeal, and retropharyngeal spaces (RPSs) are considered life threatening and are the focus of this discussion.
The submandibular space (SMS) (Fig. 180.5) consists of the sublingual and submylohyoid spaces, which communicate around the free posterior border of the mylohyoid muscle. It extends from the mucous membrane of the floor of the mouth above to the superficial layer of the deep cervical fascia below. It is bounded by the mandible both anteriorly and laterally. Superolaterally is the buccopharyngeal gap, an important opening behind the styloglossus muscle, which connects the SMS to the LPS.

The LPS (Fig. 180.6), also called the pharyngomaxillary or parapharyngeal space, is shaped like an inverted cone with its apex at the
The styloid process penetrates the space and divides it into two functional units: anterior (muscular) and posterior (neurovascular) compartments. The former lies lateral to the tonsillar fossa and connects inferomedially to the SMS. The latter contains the carotid sheath and its contents (internal carotid artery, internal jugular vein, vagus nerve, and lymph nodes), cranial nerves IX through XII, and the cervical sympathetic trunks. Both compartments abut the RPS.

The RPS, also called the posterior visceral space (see Fig. 180.4), lies between the middle layer of the deep cervical fascia, which surrounds the pharynx and esophagus anteriorly, and the alar layer of the deep cervical fascia posteriorly. It extends from the base of the skull to the level of T1 or T2 in the superior mediastinum. Laterally, it abuts the LPS. Two chains of lymph nodes that drain many structures of the head are located on either side of the midline.

Immediately posterior to the RPS is the danger space (see Fig. 180.4), so named because it is the pathway into the chest for all neck infections. It extends from the base of the skull to the diaphragms and is bounded posteriorly by the prevertebral layer of the deep cervical fascia. Involvement of this space by infection is a result of extension from the RPS or prevertebral space and can result in life-threatening complications.

The prevertebral space (see Fig. 180.4) lies between the vertebral bodies and the prevertebral layer of the deep cervical fascia. Infections at this location most often represent chronic processes arising from cervical
Etiology

Bacteria found in normal oral flora are primarily responsible for deep cervical infections. When mucosal barriers are interrupted, bacteria can penetrate into the deeper spaces. Infections are typically polymicrobial with anaerobes predominating over aerobes. Fungi and mycobacteria are uncommon etiologic agents in these infections. The role of biofilms in deep neck infections has been observed with electron microscopy, resulting in failure of antimicrobial therapy, particularly in larger abscesses [92]. Numerous bacteria naturally form biofilms, such as *staphylococcus epidermidis*, *Pseudomonas aeruginosa*, *E. coli*, *Streptococci*, *Candida*, and other gram-positive and gram-negative species [92].

Correct identification of the causal pathogen requires careful culture techniques. Several factors contribute to the difficulty of obtaining meaningful bacteriologic data. Most patients receive antibiotics before hospitalization, many deep infections resolve with empiric antibiotic therapy without the need for aspiration procedures, and cultures obtained perorally are often contaminated by nonpathogenic organisms colonizing the oropharynx [91,93,94]. With proper anaerobic collection and transport techniques, three anaerobic isolates are most commonly identified: *Peptostreptococcus*, *Fusobacterium* (mostly *F. nucleatum*), and *Bacteroides* (mostly *B. melaninogenicus*) [93,94]. Although obligate anaerobes as a class are recovered most often, aerobic streptococci (mostly *Streptococcus viridans*) and staphylococci are the most frequent individual isolates [93]. Among 148 adults, *Klebsiella pneumoniae* was found to be the most prevalent bacterial isolate [95].

Among other facultative gram-negative organisms *Escherichia coli*, *P. aeruginosa*, *K. pneumoniae*, *H. influenzae*, *Enterobacter*, *Proteus mirabilis*, *Citrobacter freundii*, and *Actinomyces* spp. have been isolated from deep cervical infections [91]. *Eikenella corrodens*, a facultative anaerobic gram-negative rod, is an emerging pathogen in head and neck infections that is uniformly resistant to clindamycin [94]. Staphylococci should be considered in deep neck infections, particularly with cases of penetrating trauma, including cervical intravenous (IV) drug use [94]. *Staphylococcus aureus*, including resistant forms (MRSA), have been found to be more prevalent among the pediatric population in younger age group with subsequent higher rate of complications, such as mediastinitis [96]. Among patients with diabetes, *K. pneumoniae* is most commonly isolated, followed by *Streptococcus* spp. [97].

When microbiologic confirmation is lacking, clinical clues may help suggest the presence of anaerobes. A foul-smelling discharge, gas
production, tissue necrosis, and abscess formation can be suggestive, but the sensitivity of these findings is low. Gram’s stain may reveal anaerobic organisms with specific morphologic characteristics (e.g., *Clostridia*, *Fusobacterium*). Because anaerobes are more fastidious, failure of the more rapidly available aerobic cultures to reveal a causative organism may suggest an anaerobic pathogen.

**Diagnosis**

It is important to distinguish the space or spaces involved by deep neck infections to allow for early recognition and prevention of potentially devastating complications. The clinical picture may be confusing because of involvement of multiple spaces and interference with the physical examination by trismus. Fever and systemic toxicity are common early symptoms. Other signs and symptoms may be helpful to localize the primary site of infection (Table 180.2) [98]. Serologic testing contributes little to the diagnostic evaluation. Although initial assessment often includes a lateral neck radiograph to screen for widening of the retropharyngeal tissues, the sensitivity of this test is lower than contrast-enhanced computed tomomography (CECT). CECT has a sensitivity of 80% to 90% [99] and a positive predicted value 76.9% for the diagnosis of deep neck infections [100]. Plain chest x-ray can be used to screen for complications such as pleural effusions, mediastinitis and pneumonia [99]. False positive CT scans may be caused by cellulitis or by metastatic cervical lymph nodes with necrosis, and thus biopsy of necrotic lymph nodes is recommended to assure these changes are caused by infection and not malignancy. The ability of CT scans to diagnose a deep neck abscess is much better when multiple spaces are involved (PPV 91.3%) than when the infection is confined to a single pocket (PPV 50%) [100]. Ultrasound is useful for superficial abscesses, which would have the added advantage of drainage and limited radiation exposure, though it is less helpful for deeper locations [99]. MRI can be more precise than CECT in multiple space involvement, though has greater acquisition time and requires more patient cooperation [100].

### Sublingual Space Infections

Infection in the SMS is exemplified by Ludwig’s angina. This is a potentially life-threatening, bilateral cellulitis originating in the SMS. It spreads rapidly by direct extension, rather than via lymphatics, and can involve the submental and sublingual spaces [101]. Glandular structures are spared, and gangrene occurs without abscess formation (see Fig. 180.5) [102]. Dental infections are the most common source, specifically those involving the roots of the second and third molar area lying immediately superior to this region [99,103]. The next most common cause is extension from an upper airway infection such as peritonsillar abscess [103]. Symptoms range from fever, malaise, submandibular swelling, erythema, to dysphagia, dyspnea, and endangerment of airway from tongue swelling, trismus, and neck swelling [101,103]. Among early cases, conservative management with antibiotics and critical care observation can be considered because endoscopically assisted nasotracheal intubation or bedside tracheostomy tube may be needed with for airway management [103].

Ludwig’s angina is essentially a clinical diagnosis. Physical examination (Fig. 180.7) reveals bilateral, firm submandibular swelling [102]; most patients with SMS involvement demonstrate soft tissue swelling, prompting further radiographic examination (Fig. 180.8). With aggressive airway management, antibiotics and surgical decompression of indurated submandibular glands, mortality from Ludwig’s angina has decreased to less than 10% [94] Mortality rates have decreased significantly because of a more effective antibiotic therapy and early airway control [7,54].

**Figure 180.7** Schematic representation of salient clinical findings of Ludwig’s angina.
FIGURE 180.8 Ludwig’s angina. Lateral radiographs of the neck obtained with soft tissue technique in a 7-year-old child. There is soft tissue swelling of the submandibular space (s), producing a smooth impression on the airway anteriorly, compressing and practically ablating the vallecula (arrowhead): the epiglottis (e) and aryepiglottic folds (a) are normal.

**Lateral Pharyngeal Space Infections**

The signs and symptoms of LPS infections are determined by which of the two compartments is affected (see Fig. 180.6). The four major clinical signs of anterior compartment involvement include systemic toxicity with high fever and rigors; unilateral trismus due to irritation of the internal pterygoid muscle; induration and swelling along the angle of the jaw; and medial bulging of the lateral pharyngeal wall with the palatine tonsil protruding into the airway [104] (Fig. 180.9). Other symptoms may include dysphagia and pain involving the jaw or side of the neck. Pain may be referred to the ipsilateral ear and may worsen with turning the head to the unaffected side, which compresses the inflamed space by contraction of the sternocleidomastoid muscle. Common sources of involvement arise from pharyngitis, tonsillitis, otitis, mastoiditis, parotitis,
and cervical lymphadenitis [94,104]. Peritonsillar abscess are a particularly common cause of this infection [104]. Extension from the SMS and RPS has also been observed.

![Figure 180.9](image)

**FIGURE 180.9** Schematic representation of salient clinical findings of lateral pharyngeal space abscess.

For infection of the posterior compartment, trismus and tonsillar prolapse are notably absent. Edema may involve the larynx and epiglottis, resulting in marked dyspnea [104]. External swelling may be visible when it spreads to the parotid space (see Fig. 180.9), but most patients have no localizing signs.

Many symptoms and signs in LPS infections are caused by the involvement of the neurovascular structures. Suppurative jugular venous thrombosis, or Lemierre’s syndrome, is the most common complication. Bacteremia and septic emboli, the most frequent consequences of this entity, occur in one half of the cases [105–107]. Suppurative subclavian thrombosis, lateral sinus thrombosis, cavernous sinus thrombosis, and metastatic infections have also been reported [104,105,107].

Signs suggestive of carotid sheath involvement include persistent
tonsillar swelling after resolution of a peritonsillar abscess, ipsilateral Horner’s syndrome, and cranial nerve IX to XII palsies [104]. Carotid artery aneurysm or rupture can present as a pulsatile mass, resulting in sentinel bleeding from the ear or pharynx after a protracted course of illness of 7 to 14 days, as hematoma of the neck or hemodynamic collapse [94] It can be result of direct inoculation of infection after intravenous drug use [94]. CT scan has been used to define neck masses, particularly in the LPS, with excellent results (Fig. 180.10) [108]. Because the complications of deep neck abscesses are potentially fatal, CT scan of the neck is indicated for all cases, especially when surgical intervention is contemplated. The scan can be extended inferiorly to include the chest and mediastinum. Ultrasound may quickly and accurately identify thrombus and perivenous changes due to supplicative adenitis [99], although pain from the probe can limit accuracy. CT findings include inflammatory changes in the perivascular space, enhancement of venous walls and the presence of thrombus within the lumen [99].

**FIGURE 180.10** Abscess in the lateral pharyngeal space. Computed tomography at the level of the hyoid bone (h), at the apex of the inverted lateral pharyngeal space cone. There is a cystic mass (arrow) with floating air bubbles and enhancing rim (arrowhead), findings virtually pathognomonic of abscess caused by gas-forming organisms. m, base of mandible.
RPS abscesses are uncommon but potentially fatal infections, most often seen in children younger than 6 years old because the lymph nodes regress with age [94,109]. The two chains of lymph nodes in this space drain adjacent muscles, nose, nasopharynx, pharynx, middle ear, eustachian tubes, and paranasal sinuses and are the source of most RPS abscesses. Among children, it is typically secondary to acute pharyngitis, whereas for adults, it can occur from penetrating injury from fish bone ingestion, nasogastric tube placement or intubation [99]. Among children, the initial symptoms include fever, irritability, and refusal to eat [94]. The neck is often stiff and sometimes tilted away from the involved side [109]. Dyspnea and dysphagia occur as the swelling increases. Adults can present with neck pain, fever, dyspnea, snoring, and nasal obstruction [94]. Respiratory distress can occur as the abscess protrudes anteriorly (see Fig. 180.4).

Among children, spontaneous rupture of a retropharyngeal abscess may result in aspiration and asphyxiation or upper airway obstruction from a combination of a child’s high larynx and anterior displacement of the pharyngeal wall [94]. Severe respiratory distress, particularly if accompanied by chest pain or pleurisy, suggests mediastinal extension.

The lateral neck radiograph can aid in making the diagnosis by its ability to detect prevertebral soft tissue swelling (Fig. 180.11). The radiograph should be a true lateral view, with the neck in full extension, and should be made during inspiration. Exhalation, crying, and swallowing, especially in children, may cause thickening of the upper cervical soft tissues. Normal dimensions have been defined as less than 7 mm in all age groups at the C2 (retropharyngeal) level and less than 14 mm in children or 22 mm in adults at the C6 (retrotracheal) level [110]. Loss or reversal of the normal cervical lordosis secondary to inflammation-induced muscle spasm also suggests an RPS infection. CT scans can be valuable as well for the diagnosis of retropharyngeal abscess. It is of paramount importance to extend the CT to include the upper mediastinum. Large paramedian nodes will be seen with central low density and an enhancing ring, whereas in cellulitis, there is symmetric low attenuation of the RPS [99].
FIGURE 180.11 Retropharyngeal abscess. Lateral neck radiograph. There is marked swelling of the prevertebral soft tissues extending from the base of the skull to the base of the neck, with bulging and anterior displacement of the airway. There is mild reversal of the normal lordosis of the neck secondary to muscle spasm. The epiglottis (e) and aryepiglottic folds (a) are normal.

The most feared complications are airway obstruction and rupture of abscess. Hence, patients with impending airway obstruction should be examined in the operating room, intubated in Trendelenberg’s position along the opposite side of the pharyngeal swelling. Needle aspiration should precede intra-oral incision and drainage [94].
Descending Infections

Any deep neck infection can have access to the posterior mediastinum and diaphragm by the common pathways of the RPS and danger space [111,112]. Descending necrotizing mediastinitis can carry a mortality of greater than 36% [112]. The process can develop within 12 hours to as long as 2 weeks from the onset of the primary infection. The diagnosis may be difficult to make early in the course of the illness. Severe dyspnea and pleuritic or retrosternal chest pain concomitant with or subsequent to the onset of symptoms of an oropharyngeal infection suggest this process. The infection may progress, producing a widespread necrotizing process extending to the diaphragms and occasionally into the retroperitoneal space; a mediastinal abscess that may rupture into the pleural cavity; or purulent pleural and pericardial effusions [112]. Suggestive physical findings include diffuse, bulky induration of the neck and upper chest associated with pitting edema or crepitation [94].

Cervical necrotizing fasciitis, a fascial infection with muscle necrosis, often without pus or abscess formation, can progress superficially along the fascial planes of the neck and chest wall [113]. Early in the course of this disease, the physical appearance may be deceptively benign. Skin erythema occurs initially and progresses to dusky skin discoloration, blisters, or bullae and eventually to visible skin necrosis [114]. Crepitation may be absent, but gas in the tissues can readily be seen using CT. Surgical exploration with wide excision is essential to determine the full extent of necrosis and to improve prognosis [113].

Infections of the prevertebral space comprises of spinal epidural collection that can result in spinal cord compression and irreversible paralysis in 4% to 22% of patients [104]. Psoas muscle collections may also be seen because of the open communication with the PVS [104].

Differential Diagnosis

Few clinical entities must be distinguished from deep cervical infections. Common causes of submandibular swelling include cervical adenitis and submandibular sialoadenitis. In the proper settings, the differential diagnosis includes anticoagulant overdose with sublingual hematoma, tumor of the floor of the mouth, superior vena cava syndrome, and angioedema. None of these presents with the classical physical findings or respiratory symptoms of SMS infection due to Ludwig’s angina.

The major entities from which LPS infection must be differentiated are peritonsillar abscess, anaerobic tonsillitis, and masticator space infections. Peritonsillar abscess becomes evident with fever and tonsillar
prolapse but without extreme toxicity, trismus, or parotid swelling [115]. Vincent’s angina is an anaerobic tonsillitis caused by *Fusobacterium necrophorum*, which produces a foul smelling discharge that forms a pseudomembrane and can be associated with bacteremia and metastatic abscesses [106]. Acute suppurative parotitis can occur as a complication of pharmacologic therapy (e.g., diuretics and anticholinergics) [115]. Reduced salivary flow allows normal oral flora to spread to Stensen’s duct and into the gland. The most common pathogen is *S. aureus*, but infection is also seen with hemolytic streptococcus, gram-negative bacilli, and anaerobes]. The mainstays of therapy are hydration, sialagogues, and often a broad-spectrum antibiotic with anti–β-lactamase activity. Despite appropriate treatment, complications may include spread to the mastoid, entrapment of the facial nerve, severe swelling of the pharynx and neck resulting in airway obstruction, and problems typical of involvement of the LPS. Mortality may approach 25% [115].

Retropharyngeal swelling can be seen secondary to tumors such as leiomyoma, hemangioma, ectopic parathyroid adenoma, or hyperplasia. It can also be as a result of prevertebral tendinitis, tortuous carotic artery, lymphatic malformations, congenital lesions such as branchial cleft cyst and fluid accumulation after radiation therapy for head and neck tumors [116]. For children presenting with fever, sore throat, nuchal rigidity, drooling, or respiratory distress, RPS abscess, severe croup, epiglottitis, and meningitis must also be considered.

**Treatment**

All patients with deep neck infections require hospitalization. Therapy has three components: airway management, IV antibiotics, and timely surgical exploration.

**Airway Management**

Establishment of an artificial airway is not universally required, but it should be done when evidence of airway obstruction exists, such as dyspnea and stridor or inability to handle secretions. The method of airway protection in patients with deep cervical infections must be individualized for the patient and to the expertise of the available personnel [117]. Upper airway obstruction is most often a complication of infections involving the SMS, for which one approach to control the airway has been tracheostomy [118,119]. Because the surgical risks of tracheotomy may be increased by the distortion of the neck with edema, cricothyroidotom has been recommended as an alternative, particularly in emergent situations [120], given that it can be performed rapidly, and
has low complication rates. Distortion of neck landmarks may equally complicate this procedure, but fewer critical structures are in proximity, which may reduce some procedure-related risks.

Endotracheal intubation can be difficult to achieve because of trismus and intraoral swelling. Trismus may be a more significant problem when infection has spread to the LPS. Blind intubation is unsafe because of the risk of trauma to the posterior pharyngeal wall, rupture of abscesses in the LPS or RPS, and possibly laryngospasm precipitating lower airway obstruction [118,119]. Intubation utilizing a flexible laryngoscope may be useful but requires a cooperative, stable patient and may therefore be useful only for selected cases [117]. Inhaled anesthesia to relieve trismus, along with an antisialagogue, may allow for intubation under direct vision [118,119]. If this is attempted, skilled personnel should be available to establish an emergent surgical airway if needed.

Antimicrobial Therapy

Antibiotic therapy should be given intravenously for all neck infections. Optimum empiric coverage is recommended with either penicillin in combination with a β-lactamase inhibitor (such as amoxicillin; ticarcillin with clavulanic acid; or piperacillin/tazobactam) or a β-lactamase–resistant antibiotic (such as cefoxitin, cefuroxime, imipenem, or meropenem) in combination with a drug that is highly effective against most anaerobes (such as clindamycin or metronidazole) [90,94]. Vancomycin should be considered for patients with immune dysfunction, neutropenia, and in IV drug abusers at risk for infection with MRSA [94]. If needed, other agents including linezolid, daptomycin, and quinupristin/dalfopristin can be substituted in place of vancomycin. The addition of gentamicin for effective Gram-negative coverage against K. pneumoniae, which is resistant to clindamycin, is highly recommended for diabetic patients with intact renal function [94]; Parenteral antibiotic therapy should be continued until the patient has been afebrile for at least 48 hours, followed by oral therapy using amoxicillin with clavulanic acid, clindamycin, ciprofloxacin, trimethoprim–sulfamethoxazole, or metronidazole [94]. The antibiotic regimen can be de-escalated based on culture data.

Resection of a thrombosed vein is not widely recommended but may be unavoidable in a patient who deteriorates despite drainage of the LPS, or in one whose vein is frankly suppurative [104].
Surgery

Conservative therapy using antibiotics and selective needle aspirations can be successful [93,94,121]. In general, if signs of clinical improvement are not observed after treatment with IV antibiotics for 24 to 48 hours, then reimaging and surgical intervention are likely warranted. Surgical drainage is the cornerstone of treatment for anterior LPS, RPS, and PVS infections [104]. For SMS infections, an initial trial of antibiotics can be considered. Selected patients, such as those with cellulitis, abscess size less than 3 cm, and without involvement of more than one danger space and general stability may not require surgical intervention [93]. Once surgical intervention is indicated, dental extraction is included as well [93,104]. Recommendations for surgical treatments are individualized and can include cervical drainage; thoracotomy with radical surgical debridement of the mediastinum; and excision of necrotic tissue, decortication, and irrigation [122]. A less invasive thoracoscopic approach has also been described [123].

Pneumonia is a common community- and hospital-acquired infection that is managed in the intensive care unit (ICU) when it leads to acute respiratory failure or septic shock, or when it complicates the course of an otherwise serious illness. Modern medical technology has not been able to eliminate this infection. Rather, it has promoted its emergence by the application of novel, life-sustaining therapies in specific at-risk populations who have impairments in respiratory tract host defenses. This chapter reviews the scope of the problem among seriously ill patients.

Sir William Osler described pneumonia as “the captain of the men of death.” The Centers for Disease Control and Prevention (CDC) surveillance data from 2010 reported 1.1 million pneumonia-related discharges with an average of 5.2 days of hospital stay [1]. There is a significant economic impact associated with pneumonia and the greatest burden of care, which is linked with inpatient management. One recent study estimated the direct and indirect costs of caring for pneumococcal pneumonia per year in patients over 50 years of age to be $3.7 billion and $1.8 billion, respectively [2]. Since the discovery of penicillin in 1928, antibiotics have remained the mainstay of disease management, but the indiscriminate use of broad-spectrum antibiotics has resulted in the emergence of drug-resistant pathogens, even among common organisms such as *Streptococcus pneumoniae*. The U.S. Government has recently announced the “National Action Plan for combating Antibiotic-resistant Bacteria” in 2015 [3].

Community-acquired pneumonia (CAP) refers to pneumonia developing in the outpatient setting or within 48 hours after hospitalization, whereas nosocomial pneumonia (NP) by definition occurs at least 48 hours after admission [4,5]. NP, or hospital-acquired pneumonia (HAP), includes ventilator-associated pneumonia (VAP) which develops at least 48 hours after endotracheal intubation. Health care–associated pneumonia (HCAP) is pneumonia developing in patients with previous exposure to the health care environment, such as nursing
homes, dialysis centers, or previous hospitalization for more than 2 days in the preceding 3-month period. These individuals can become infected with hospital-associated drug-resistant pathogens and the latest treatment guidelines recommended initial, empirical, broad-spectrum antibiotics targeting resistant pathogens [4]. However, it is now clear that this population represent a heterogeneous group, and that some patients can be treated with antimicrobials targeted at community acquired pathogens, so the classification of HCAP is in flux [6].

The incidence of pneumonia among hospitalized patients is directly related to the degree of underlying systemic illness, being more common in medical than in surgical patients, and in those requiring prolonged mechanical ventilation [4]. Certain patient populations are at increased risk for pneumonia, primarily as a result of disease-associated impairments in lung host defenses. These include the elderly and those with cardiac disease, alcoholism, chronic obstructive pulmonary disease (COPD), congestive heart failure (CHF), malnutrition, head injury, cystic fibrosis, bronchiectasis, malignancy, splenic dysfunction, renal failure, liver failure, diabetes mellitus, and other immunosuppressive illnesses or therapies [4,6]. In addition, hospitalized patients often receive therapeutic interventions that predispose them to pneumonia, including antibiotic therapy, enteral feeding, endotracheal intubation, tracheostomy, and the use of certain medications (such as corticosteroids, aspirin, digitalis, morphine, and pentobarbital) [6].

The mortality implications of pneumonia (along with influenza) rank it as the eighth leading cause of death in the United States, the sixth leading cause of death in those older than 65 years, and the number one cause of death from infectious diseases [5]. Although CAP can vary from a mild to a severe illness, those who enter the ICU with this infection have a mortality rate that can vary from 20% to greater than 50% [7]. The indications for ICU admission and the definitions for severe CAP are changing, and with good reason, since the later in the hospital course that the ICU is used, the higher the mortality [8]. Among patients with severe CAP, delayed admission to the ICU or delayed intubation (after 3 days), are associated with increased mortality and longer length of ICU stay [9,10]. Although sepsis increases CAP mortality, bacteremia by itself is not a mortality risk [11].

Poor prognostic factors associated with CAP mortality include the presence of multilobar pneumonia (bilateral may be worse than unilateral multilobar), respiratory rate greater than 30 breaths per minute on admission, severe hypoxemia, abnormal liver function, low serum albumin, signs of clinical sepsis, and delayed or inappropriate antibiotic therapy [5,12]. There is also a biphasic relation with platelet count, with increased mortality outside the range of 100,000 to 400,000 per μL [13,14]. Arterial partial pressure of carbon dioxide (PaCO₂ <35 or >45
mm Hg) on admission is also related to increased mortality in hospitalized CAP patients, independent of the presence of COPD [13,14]. Hospitalized pneumonia patients are also at increased risk of cardiac ischemia and arrhythmias, and the event may be abrupt and without warning potentially causing cardiorespiratory arrest [15]. In a recent study evaluating factors predicting in-hospital versus postdischarge mortality of hospitalized pneumonia patients aged 65 or older, mortality was 12.1% within 30 days of admission (52.4% of the deaths occurred during the hospital stay) [16]. In that study, the timing of death was unrelated to baseline patient demographic factors or comorbidities, but in-hospital mortality was related to the severity of illness [16].

The adverse prognostic factors discussed above are particularly applicable to the elderly, and those with nursing home–acquired pneumonia often have a higher mortality rate than those with simple CAP [7]. One factor that may explain this finding is that older patients often have atypical clinical presentations of pneumonia, which may lead to their being diagnosed at a later, more advanced stage of illness, resulting in an increased risk of death. In general, the mortality associated with severe CAP is a reflection of how accurately the ICU is used, what organisms are causing the infection, what complications develop in the hospital, and how effective is the initial empiric therapy [17] (Table 181.1).

NP is associated with a high mortality rate (ranging from 20% to 50%) and a significant economic impact with additional hospital costs of ≥10,019 to 40,000 USD [18,19]. HAP has been the second most common nosocomial infection in the United States accounting for up to 25% of all ICU infections and for more than 50% of the antibiotics prescribed [4]. However, in recent years, with the application of effective prevention strategies, the frequency of VAP has been declining. The presence of HAP increases hospital stay by an average of 7 to 9 days per patient [6]. Available data suggest critically ill patients who develop VAP appear to be twice as likely to die compared with similar patients without VAP (pooled odds ratio [OR], 2.03; 95% confidence interval, 1.16 to 3.56) [18].

Factors associated with NP mortality include severity of illness, poor functional status before the onset of mechanical ventilation, development of shock, acute renal failure, worsening of hypoxemia during the period of mechanical ventilation, inappropriate therapy, delay in the initiation of therapy, failure to de-escalate therapies, prolonged mechanical ventilation, coma on admission, chronic liver disease, nonsurgical primary diagnosis, bilateral infiltrates, septic shock, multiple system organ failure, and use of prior antibiotic therapy [6]. Patients usually develop HAP because of an underlying chronic illness, and thus the question arises, if they die, whether their death was due to the pneumonia itself or a result of the underlying, predisposing illness. This issue of “attributable mortality” has been studied, and in older studies, as many as 60% of those who die did so as a direct result of their pneumonia [18]. However, more recent data suggest a much lower attributable
mortality, and lower death rates from pneumonia among patients with ARDS than previously reported. In a study including 4,479 ventilated patients, mortality related with VAP (24.1%) was not substantially different from mortality in non-VAP patients (23.1%) [20]. However, these studies were performed on patients already on antibiotics; and thus, it is difficult to differentially evaluate the impact of pneumonia on mortality, as inappropriate or no therapy would increase mortality. Bacteriology is another important factor adding to mortality in HAP, with Kollef et al. reporting a high attributable mortality for late-onset VAP caused by potentially drug-resistant organisms such as \textit{Pseudomonas aeruginosa}, \textit{Acinetobacter} spp, and \textit{Stenotrophomonas maltophilia} [21]. Thus, similar to the data with severe CAP, mortality in NP is also affected by patient characteristics, bacteriology, and the efficacy of therapy.

**TYPES OF PNEUMONIA ENCOUNTERED IN THE INTENSIVE CARE UNIT**

Serious pneumonia occurs when a potential pathogen overwhelms a patient’s host defenses, and then, because of either overwhelming infectious challenge or an excessive inflammatory response to infection, the patient develops respiratory failure or septic shock. Certain pathogens are so virulent that they can even overcome an intact, and normal, host defense system, as is the case with epidemic viral illness. Normal host defenses can also be overcome if the inoculum of the pathogen is large (as with massive aspiration), but smaller inocula can be pathogenic if disease-associated factors interfere with immune function. Certain patients seem to become ill because of an excessive inflammatory response to a localized infection, and genetic differences of the immune system are one increasingly implicated explanation.

**Community-Acquired Pneumonias Leading to Intensive Care Unit Admission**

Although less than 20% of all patients with CAP require hospitalization, those patients ill enough to enter the hospital may have a substantial mortality rate, and mortality is even greater for those admitted to the ICU. For a general ICU population, the mortality rate of CAP, reported in a meta-analysis of 788 patients, was just more than 35%, but other series have reported lower rates [12]. Pathogens that have been described as causing severe CAP include \textit{S. pneumoniae} (pneumococcus), \textit{Legionella pneumophila}, \textit{Haemophilus influenzae}, enteric Gram-negative bacteria, \textit{Staphylococcus aureus}
Definition of Severe CAP and Prognostic Factors/Scoring Systems

Although “severe” CAP does not have a uniform definition, the term has been used to refer to patients with CAP who require ICU care. Some investigators have focused on defining patients with CAP who need intensive respiratory or vasopressor support (IRVS), independent of the site of admission [5,7]. Torres et al. [22] estimated that CAP accounted for 10% of all admissions to an ICU over a 4-year period, and that these patients were admitted directly to the ICU 42% of the time, after admission to a hospital ward 37% of the time, and after transfer from another hospital 21% of the time.

Over the past decade, a number of studies have examined prognostic scoring systems for patients with CAP. In general, there are two widely used approaches, the Pneumonia Severity Index (PSI) and the British Thoracic Society approach (CURB-65). Each uses a point scoring system to predict a patient’s mortality risk, with the CURB-65 being simpler and more focused on acute illness parameters, whereas the PSI is a more complex system that incorporates measurements of both chronic and acute disease factors [7]. Although both tools predict mortality risk, neither is a direct measure of severity of illness. For example, as many as 37% of those admitted to the ICU in one study were in PSI classes I–III, pointing out that even those with a low risk for death (which PSI can measure) may benefit from aggressive intensive care support [23]. Conversely, patients in higher PSI classes do not always need ICU care if they fall into these high mortality risk groups because of advanced age and comorbid illness in the absence of physiologic findings of severe pneumonia.

In another study, both tools were applied to the same patients, and each was similarly accurate for identifying low-risk patients [24]. However, the CURB-65 was more discriminating for predicting mortality risk of patients with more severe illnesses. This approach gives one point
for each of five abnormalities: confusion, elevated blood urea nitrogen (BUN) (>19.6 mg per dL), respiratory rate 30 per minute or more, low blood pressure (BP) (either systolic <90 mm Hg or diastolic ≤60 mm Hg), and whether the patient is at least 65 years old. If three of these five criteria are present the predicted mortality rate is greater than 20%, and these patients are generally considered for ICU admission [25]. A similar approach has been developed by the Japanese Respiratory Society, using the A-DROP scoring system, that assesses Age (male ≥70 years, female ≥75 years); Dehydration (BUN ≥210 mg per L); Respiratory failure (SaO(2) ≤90% or PaO(2) ≤60 mm Hg); Orientation disturbance (confusion); and low blood Pressure (systolic BP ≤90 mm Hg) [26].

España et al. developed a severe pneumonia scoring system (CURXO-80), based on data from 1,057 patients in Spain, suggested that the need for ICU admission could be defined by the presence of one of two major criteria (arterial pH <7.39 or a systolic BP <90 mm Hg), or the presence of two of six minor criteria, which included confusion, BUN greater than 30 mg per dL, respiratory rate greater than 30 per minute, PaO2/FiO2 ratio less than 250, multilobar infiltrates, and age 80 years or older. This approach gave different point values to each abnormality, and when severity criteria were met, the tool was 92% sensitive for identifying those with severe CAP and was more accurate than the PSI or the CURB-65 [27]. Another tool, SMART-COP, was developed to predict the need for IRVS using eight clinical features, in which the acronym referred to systolic BP less than 90 mm Hg, multilobar infiltrates, albumin less than 3.5, respiratory rate elevation (>25 for those younger than 50 years, and >30 for those older than 50 years), tachycardia (>125 per minute), confusion, low oxygen (<70 mm Hg if younger than 50 years or <60 mm Hg if older than 50 years), and arterial pH less than 7.35 [28]. Using specific cutoffs, the sensitivity for the need for IRVS was 92.3% and the specificity of 62.3%, with a positive and negative predictive value of 22% and 98.6%, respectively. Both PSI and CURB-65 did not perform as well overall.

Recently, the accuracy of prognostic scoring systems has been enhanced by biomarker measurements. Most data have focused on procalcitonin (PCT), a “hormokine” that has increased plasma concentrations in the presence of severe bacterial infections, but not in viral illness. Masiá et al. reported PCT levels to correlate well with the PSI score and the development of complications such as empyema, mechanical ventilation, and septic shock in a study of 185 patients [29]. Krüger and associates found that PCT identified low-risk patients in all severity classes, and that the finding of a low PCT value had a 98.9% negative predictive value for mortality, regardless of the results of prognostic scoring tools [30]. Similarly in a study of 1,651 patients admitted with CAP, there were 546 in high PSI classes (IV and V), but in
the 126 of these who had low PCT levels, only two died, suggesting the advantage of combining serum markers with the commonly used prognostic indices [31].

Although there are no absolute criteria for severe pneumonia, or need for ICU admission, in the 2007 American Thoracic Society/Infectious Society Diseases of America (ATS/IDSA) guidelines, severe CAP was defined as the presence of one of two major criteria (need for mechanical ventilation, or septic shock requiring pressors) or the presence of three of nine minor criteria [5]. These minor criteria were a PaO$_2$/FiO$_2$ ratio of 250 or less, respiratory rate 30 per minute or more, confusion, multilobar infiltrates, systolic BP less than 90 mm Hg despite aggressive fluid resuscitation, BUN greater than 20 mg per dL, leukopenia (<4,000 cells per μL), thrombocytopenia (<100,000 cells per μL), and hypothermia (<36°C) [5]. In a study of 2,102 CAP episodes over 7-year period, the ATS/IDSA predictive rule had a sensitivity of 71% and a specificity of 88% for determining the need for ICU admission [32]. Phua and colleagues showed that the ATS minor criteria had greater discriminatory power in the prediction of severity, ICU admission, and mortality than the PSI and CURB [33]. Brown and associates noted that both the positive and negative predictive value of minor criteria exceeded 80% if four criteria were used to define the need for ICU admission rather than just three criteria [34]. In a recent study, investigators simplified the ATS/IDSA criteria by excluding variables that occurred in <5% of cases—leukopenia, thrombocytopenia, and hypothermia, and noted similar predictive value for mortality and intensive care admission as compared to the original ATS/IDSA criteria [35]. In the same study, addition of another variable—acidosis (pH <7.35) improved the prediction for mortality and for ICU admission.

Another score, the “CAP—PIRO score” is calculated within 24 hours of ICU admission and assigns 1 point for each variable: comorbidities (COPD, immunocompromise), age greater than 70 years, multilobar opacities on chest radiograph, shock, severe hypoxemia, acute renal failure, bacteremia, and acute respiratory distress syndrome [36]. Patients are stratified into four levels of risk, and the score performed well as a 28-day mortality prediction tool in patients with CAP requiring ICU admission, with a better performance than APACHE II and the IDSA/ATS criteria. The Risk of Early Admission to ICU (REA-ICU) index was derived from a data set of nearly 5,000 patients and is helpful as a tool on admission to identify patients who had no obvious indication for ICU management, but subsequently required ICU care. It categorizes individuals into four risk groups based on 11 criteria independently associated with ICU admission: male gender, age younger than 80 years, comorbid conditions, respiratory rate of 30 breaths per minute or higher, heart rate of 125 beats per minute or higher, multilobar infiltrate or
pleural effusion, white blood cell count less than 3 or 20,000 per μL or above, hypoxemia (oxygen saturation <90% or arterial partial pressure of oxygen (PaO₂) <60 mmHg), blood urea nitrogen of 11 mmol/L or higher, pH less than 7.35 and sodium less than 130 mEq/L [37]. The mortality and likelihood of needing ICU care increased with each risk group with the highest in class IV with a score ≥9. In a recent validation study including 850 CAP patients, who had no obvious need for ICU care on admission, the REA-ICU index performed better than PSI but was similar to other tools (like SMART-COP, CURXO-80, the 2007 IDSA/ATS minor severity criteria, and CURB-65) at defining the need for early ICU admission [38].

CAP Prognostic Factors Defined After Initial Management

The above discussion has focused on data available on admission to guide the site of care decision, but after admission, as the results of cultures become available, and therapy (accurate or not) is given, these events can impact prognosis. Garau et al. found that late and overall CAP mortality are reduced when patients have negative blood cultures, and when antibiotic therapy is given according to guidelines [39]. Among patients with severe CAP, the most important prognostic finding during therapy is radiographic progression [22]. Ineffective initial empirical therapy has also been identified as a potent predictor of death, being associated with a 60% mortality rate, compared with an 11% mortality rate when patients received initial effective therapy [40]. Similarly, among other studies of CAP, the use of a combination of a β-lactam and a macrolide antibiotic was associated with a lower mortality than when other therapies were given, and the use of guideline compliant therapy was associated with a reduced duration of mechanical ventilation [5,41]. In the setting of severe pneumococcal bacteremia, the use of combination therapy is associated with reduced mortality, compared with monotherapy, particularly among patients treated in the ICU [5]. Not only must initial therapy be accurate, it must be timely, and in patients with septic shock (from all sources, including pneumonia), mortality increases by 7% for each hour of delay in initiating therapy [42]. Retrospective data have also shown a reduced mortality for admitted CAP patients who were treated within 4 hours of arrival to the hospital compared with those who were treated later [5].
bacteriology is most evident when patients with CAP are infected with drug-resistant organisms, particularly drug-resistant pneumococcus. Studies have defined the clinical features of patients at risk for drug-resistant pneumococcus (drug-resistant *S. pneumoniae* [DRSP]) and these include older than 65 years, β-lactam therapy in the past 3 months, multiple medical comorbidities, alcoholism, nosocomial acquisition, and contact with a child in day care [5]. Most investigators have found no difference of mortality for patients infected with resistant or sensitive organisms, after controlling for comorbid illness [43], although patients with resistant organisms may have a more prolonged hospital stay, and suppurative complications such as empyema [44], and the presence of high-level penicillin resistance has been associated with increased mortality among those infected with HIV [45].

Recently, the definitions of resistance have been changed for nonmeningeal infection, with sensitive being defined by a penicillin minimum inhibitory concentration (MIC) ≤2 mg/L, intermediate as an MIC of 4 mg/L, and resistant as an MIC ≥8 mg/L [46]. Although the clinical impact of resistance on outcomes such as mortality was hard to show using older definitions, with the new definitions of resistance, very few pathogens will be defined as resistant, but those that are, may affect outcomes.

### Nosocomial Pneumonia in the Intensive Care Unit

#### Risk Factors for HAP and VAP

As mentioned, pneumonia is the nosocomial infection most likely to contribute causally to the death of patients, particularly those treated with mechanical ventilation (VAP). Risk factors for this infection fall into four categories: the underlying primary critical illnesses leading to ICU admission; coexisting medical illness; factors associated with therapies that are frequently used in the ICU; and malnutrition. Thus, some of the common conditions associated with NP include risk factors present on admission such as immune-suppressive illness, risk of aspiration (coma and impaired consciousness), serious comorbid illnesses (chronic heart or lung disease, renal failure, malignancy, and diabetes mellitus), ARDS, malnutrition (serum albumin <2.2 mg per dL), obesity, age greater than 60 years, smoking and drug abuse, need for major surgery, and recent major trauma or burns. Other nonmodifiable risk factors that increase the risk of NP are treatment related such as prior antibiotic therapy, immune-suppressive therapy (including corticosteroids), need for multiple transfusions, transport out of the ICU, mechanical ventilation with positive end-expiratory pressure (PEEP), tracheostomy, nasogastric tube use, supine position in the first 24 hours after admission, and
intestinal bleeding prophylaxis [4,47].

Among ICU patients, nearly 90% of episodes of HAP occur during mechanical ventilation. Further, intubation increases the risk of acquiring pneumonia by as much as 6- to 20-fold [4]. Older studies estimated that the risk of NP was 1% per day of mechanical ventilation, but other data show a risk of 3% per day for the first 5 days, 2% per day for days 6 to 10, and 1% per day for days 11 to 15[48]. Although VAP occurs in 9% to 27% of all intubated patients, since many patients are intubated for only a short time, up to half of all VAP episodes begin within the first 4 days of mechanical ventilation (early-onset pneumonia) [4].

The relation between pneumonia and ARDS is particularly interesting. In older studies, as many as one-third of all cases of ARDS were the result of pneumonia, but secondary pneumonia was the most common nosocomial infection acquired by patients with established ARDS [4]. When patients with ARDS develop pneumonia, it is generally a late event, occurring after at least 7 days of mechanical ventilation, and when it occurs, it can be the start of a progressive downhill course characterized by multiple organ failure [4]. Using quantitative diagnostic methods, Chastre et al. found an incidence of 55% of VAP among patients with ARDS; however, there were no significant differences of survival between ARDS patients with and without VAP [49]. Thus, NP among patients without ARDS is clearly associated with a higher mortality; there is insufficient data to substantiate an increased mortality due to pulmonary infection for patients with ARDS, partly due to a high intrinsic mortality related with ARDS.

**Health Care–Associated Pneumonia**

HCAP refers to patients who develop infection while having contact with the health care environment, such as those residing in nursing homes, those treated in dialysis units, patients who have been in the hospital in the past 90 days, and those getting home infusion therapy or home wound care (Table 181.2), and some of these patients are at risk for infection with multidrug-resistant (MDR) organisms. This has also been addressed in the 2005 ATS/IDSA guidelines as a form of HAP, but some investigators prefer to consider it a form of CAP in complex hosts [4]. HCAP patients with severe illness or poor functional status as defined by activities of daily living score, or who are taking immunosuppressive medications, are at increased risk of developing MDR infections, and need broad-spectrum empiric antimicrobial therapy. However, recent studies have shown that patients who qualify as having HCAP are a heterogeneous population, and that when HCAP patients are managed in the ICU, the frequency of MDR pathogens is much greater than when
they are not as ill and do not need ICU care [50].

PATHOGENESIS OF PNEUMONIA

Normal Host Defenses

When an organism enters the respiratory tract, it encounters a host defense system designed to repel and remove it from every anatomic site in the airway. Pneumonia develops when the size of the organism inoculum overcomes the host defense system, when the organism is so virulent that it cannot be repelled, or when the patient is so impaired that he/she is unable to resist an organism type or inoculum size that could ordinarily be handled by a fully functioning host defense system. With a variety of acute illnesses, such as malnutrition, uremia, and general surgery, Gram-negative bacteria can bind more avidly to the oral epithelium, and colonization can occur, the first step toward lower respiratory tract infection [51].

The lower respiratory tract (starting beneath the vocal cords) has a complex host defense system that keeps this site sterile for normal people, although recent studies of the respiratory microbiome have questioned whether this site is ever free of bacteria. For the lower respiratory tract to become infected, organisms must overcome the physical barrier of the vocal cords and the tracheobronchial protective mechanisms of cough, bronchoconstriction, airway angulation, and the upward transport of the mucociliary blanket. Protective substances in respiratory secretions include IgA, the predominant immunoglobulin of the upper airway; IgG, which dominates in the lower respiratory tract; complement; lysozymes; surfactant; and fibronectin [52]. The resident phagocytic cell of the lower respiratory tract is the alveolar macrophage, but its function can be augmented by the production of inflammatory cytokines which can promote the recruitment of blood neutrophils and the development of cell-mediated and humoral immunity.

In the setting of focal lung infection, the cytokine inflammatory response is normally localized to the site of initial infection [53]. Severe pneumonia occurs when the inflammatory response is not localized (due to overwhelming infection or inappropriate bilateral inflammation) and the inflammatory response extends to the systemic circulation (sepsis syndrome). The innate immune response is organized to recognize pathogens and initiate an immune response. Pathogen recognition is mediated by toll-like receptors for Gram-negative bacteria and their activation contributes to pathogen-stimulated production of interleukin 1 (IL-1) or tumor necrosis factor (TNF). When pathogens are recognized through these mechanisms, nuclear factor κB is produced by inflammatory cells, which in turn leads to cytokine production that can
recruit more inflammatory cells. In addition, the lower airway handles individual pathogens in specific ways. For example, *S. aureus* is removed by resident alveolar macrophages, whereas certain enteric Gram-negative bacteria and the pneumococcus require the recruitment of neutrophils (presumably in response to interleukin-8) to be cleared [53]. Cell-mediated immunity is required to resist infection with *L. pneumophila* and *M. tuberculosis*. Viruses are handled somewhat differently from bacteria, and important factors in defense against these agents include the alveolar macrophage, neutralizing antibodies (IgG, IgA, and IgM), cytotoxic T lymphocytes, and cytokines such as the interferons. Specific genetic immune impairments or acquired immune dysfunction can cause specific aspects of the inflammatory response to malfunction and lead to infection with specific, predictable pathogens.

**How Microorganisms Reach the Lung**

Bacteria and other infectious agents can reach the lung by inhalation from ambient air, hematogenously from distal sites of infection, by direct extension or exogenous penetration, and by aspiration from a colonized oropharynx and nasopharynx. Inhalation is an uncommon route of organism entry except for pathogens such as *L. pneumophila*, viruses, and *M. tuberculosis*. Hematogenous spread can occur with septic emboli from such sites as the valves of the right cardiac chambers. Exogenous penetration is an unlikely route of bacterial entry but can occur, for example, with extension of an abdominal infection into the pleural space and then the lung parenchyma. Most pneumonias result when microorganisms are aspirated from a previously colonized oropharynx. The source of bacteria that colonize the upper airway is most likely the patient’s own lower intestinal flora, but the nasal sinuses and stomach can also harbor bacteria that can subsequently reach the lung. The coexistence of nosocomial sinusitis and pneumonia has been documented, often with the same organisms, and both infections can be promoted by the presence of a nasogastric or nasotracheal tubes [4].

In addition to promoting sinusitis, the endotracheal tube and the nasogastric tube can also serve as additional pathways for bacterial entry to the lung. Insertion of an endotracheal tube allows micro-organism direct access to the lung from the hands of the ICU staff, thereby avoiding the defense mechanisms present above the vocal cords. Any organisms that reach the inside of the endotracheal tube can proliferate to large numbers because this site is free from host defenses, and a biofilm commonly lines the interior of the endotracheal tube and can contain as many as $10^6$ organisms per cm of the tube surface [54]. These organisms can reach the lung every time an intubated patient is suctioned. A silver-coated endotracheal tube with antibacterial properties was shown to
reduce the incidence of VAP, but had no impact on mortality \[55\]. In a recent prospective study, investigators found endotracheal tubes to be coated with biofilm, as early as after 24 hours of intubation, and the biofilm was not associated with the duration of intubation, the administration of selective digestive decontamination (SDD), systemic antibiotics, or immunosuppression. In that study, the persistence of biofilm was commonly associated with treatment failure for VAP \[56\]. Another factor in VAP pathogenesis is the ventilator circuit tubing, which can easily be contaminated by large numbers of bacteria \[4\]. Interestingly, the ventilator circuits are usually contaminated by the patient, as the circuit becomes colonized in large numbers, as bacteria proliferate in the water condensate in the tubing. If handled carefully, the circuits are not a major source of pneumonia pathogens, and the incidence of pneumonia is not increased even when ventilator circuit tubing is never changed during the course of therapy \[4\].

The gastrointestinal tract, particularly the stomach, can serve as a reservoir for bacteria, and several investigators have shown that Gram-negative bacilli can move retrograde from the stomach to the oropharynx and then antegrade into the lung \[57\]. The stomach can be the source of 20% to 40% of the enteric Gram-negative bacteria that colonize the trachea of intubated patients, but it is difficult to determine if these colonizing gastric bacteria also lead to pneumonia. One of the ways that the stomach can be an important source of pneumonic organisms is through the mechanism of reflux and aspiration. When a nasogastric tube is used for feeding, it can promote aspiration, especially when a large-bore tube is used with a bolus feeding method rather than with a continuous infusion of enteral nutrients, and when the patient is kept in a supine position \[58\]. When a nasogastric tube is present, it may promote pneumonia if the gastric contents have a pH above 4 to 6, as can occur with the use of antacids, \(\text{H}_2\) blockers, and enteral feeding. An elevated pH can increase the number of Gram-negative bacteria in the stomach, increasing to as many as 1 to 100 million per mL of gastric juice, and elevation of gastric pH has been reported as a risk factor for NP, although not in all studies \[59\]. The Canadian Critical Care Trials Group reported that acidified enteral feeds preserve gastric acidity and substantially reduce gastric colonization among critically ill patients; however, in one study, there was no impact on the incidence of pneumonia with this intervention \[59\]. Increases of gastric volume can be detrimental and promote aspiration, thus accounting for the observation that when continuous enteral feeding leads to an elevation of gastric pH (and presumably an elevation of gastric volume), the incidence of pneumonia is higher than when continuous feeding is used but does not raise pH \[60\]. Another way to minimize the impact of the stomach and to avoid aspiration is to keep patients in a semierect position whenever possible,
particularly because the supine position can favor aspiration when a nasogastric tube is in place [58]. However, this position may not favor secretion clearance from the lung, and the lateral Trendelenburg position may be better for this purpose.

---

**Airway Colonization and Nosocomial Pneumonia**

Colonization (the persistence of organisms in the absence of a host response and without an adverse effect to the host) of the respiratory tract by enteric Gram-negative bacilli is the first step toward the development of NP. Risk factors for Gram-negative colonization of the upper and lower respiratory tract are similar and include antibiotic therapy, endotracheal intubation, smoking, malnutrition, general surgery, and therapies that raise gastric pH [52]. Additional risk factors for oropharyngeal colonization include azotemia, diabetes, coma, hypotension, advanced age, and underlying lung disease. Additional risk factors for tracheobronchial colonization include chronic bronchitis, cystic fibrosis, ciliary dysfunction, tracheostomy, bronchiectasis, acute lung injury, and viral infection [51]. The distinction between colonization and infection among mechanically ventilated patients is less clear than in the past, with recognition and focus on ventilator-associated tracheobronchitis (VAT) [61]. Some patients who are mechanically ventilated can have high concentrations of pathogenic organisms in the tracheobronchial tree, in the absence of pneumonia, yet may become clinically ill with purulent sputum due to VAT, and therapy could potentially prevent some from progressing to VAP.

One pathogenetic mechanism that links many of the clinical risk factors for upper and lower airway colonization is a cell–cell interaction termed bacterial mucosal adherence. Many clinical disease states can alter the oropharyngeal or tracheal epithelium, making the cell surface more receptive for binding by such bacteria as *P. aeruginosa* [51]. Diseases that result in an increased number of oropharyngeal and tracheal cell bacterial receptors are many of the same processes that promote colonization of these sites [51]. One study of intubated patients demonstrated the rapidity with which the endotracheal tube itself became colonized with enteric Gram-negatives and found that colonization took place despite the use of bacterial filters in the ventilator circuit [62]. Colonization is a common finding among intubated patients, and the presence of potential pathogens in the respiratory secretions of intubated patients is to be expected, and does not require therapy unless there are clinical signs of infection.
Host Defense Impairments in Acute and Chronic Illness that Predispose to Pneumonia

Many systemic diseases increase the risk of pneumonia as a result of disease-associated malfunctions in the respiratory host defense system, including ARDS, sepsis, CHF, malnutrition, renal failure, diabetes mellitus, chronic liver disease, alcoholism, cancer, and collagen vascular diseases [63]. In addition, many illnesses can be complicated by pneumonia because they require therapy with medications that interfere with immune function. Several studies have shown that acute and chronic malnutrition (Table 181.3) can increase the risk of bacterial and viral infections both in and out of the hospital. Genetic variation may explain why patients, who have certain inherited patterns of immune responses, are more prone to severe forms of pneumonia, and even mortality, than others. CAP severity is increased with genetic changes in the IL-10-1082 locus that are often present along with changes in the TNF-α-308 locus. Another genetic change associated with an increased risk of septic shock from CAP is a modification of heat shock protein 70-2 [64]. Currently, there are a large number of genes that are associated with the severity and outcome of CAP, but the clinical application of this information is not yet well defined. One recent observation about gender differences in the immune response was that men have a higher degree of systemic inflammation on admission for CAP (higher levels of TNF, IL-6, and IL-10), and that higher levels of these mediators increased pneumonia mortality risk [65]. Recently, Rautanen and colleagues reported the first Genome-wide association studies (GWAS) on survival from sepsis due to pneumonia in three independent cohorts of patients admitted to ICU [66]. Of more than 6 million single nucleotide polymorphisms (SNPs) examined, the authors noted common variants in the FER gene (one C/T SNP in chromosome 5) to be strongly associated with survival [66].

ETIOLOGY OF PNEUMONIA

Community-Acquired Pneumonia

Even with extensive diagnostic testing, a specific etiologic agent can be identified in only approximately 50% of pneumonias that develop outside of the hospital, although the rate of pathogen recovery may be higher among intubated and mechanically ventilated patients [67]. Although the exact incidence of viral pneumonias is unknown, these agents may account for up to one third of all community-acquired cases. The most common pathogen identified in pneumonias arising out of the hospital is the pneumococcus, and among the elderly, although pneumococci are still the most common pathogens, enteric Gram-negative organisms may be responsible for 20% to 40% of all cases of pneumonia, and anaerobes and *H. influenzae* are other common agents [68]. However, age alone has little impact on the bacterial etiology of CAP, but rather, the comorbid illnesses that become more common in the elderly affect bacteriology [69]. The most common CAP pathogens leading to ICU admission (severe pneumonia) are pneumococcus, *L. pneumophila*, epidemic viruses (influenza), *S. aureus* (including methicillin-resistant *S. aureus* [MRSA]), and enteric Gram-negative bacilli, including, for some patients, *P. aeruginosa* [17]. The incidence of CAP caused by the USA 300 clone of *S. aureus*—community-acquired MRSA (CA-MRSA) is on the rise, but the exact frequency and the impact on mortality and other outcomes remain to be defined [70]. Although Gram-negatives are more common in VAP and HCAP than in CAP, risk factors for Gram-negative pneumonia (in addition to nursing home residence, an HCAP risk factor) are cardiac disease, smoking history, and clinical features of severe illness including hyponatremia, septic shock, and severe tachypnea [71].

Other pathogens that can lead to respiratory failure include *H. influenzae*, pathogens associated with aspiration (such as anaerobes), *P. jiroveci*, *tuberculosis*, varicella, and respiratory syncytial virus. Mixed infection occurs in more than 10% of patients with CAP requiring hospitalization, and in one study, in patients with mixed CAP, *S. pneumonialae* was the most prevalent microorganism (44 out of 82; 54%) [72]. In that study, the most frequent combination was *S. pneumonialae* with *H. influenzae* (17 out of 82; 21%), and influenza A occurred with *S. pneumonialae* in 5 out of 28 (18%). Of note, patients with mixed pyogenic
Pneumonia more frequently developed shock when compared with patients with single pyogenic pneumonia (18% vs. 4%) [72].

Polymicrobial infection with viruses and bacteria is not uncommon in patients with severe pneumonia. In a recent study, investigators reported the role of viruses in 198 patients with severe pneumonia (64 with CAP and 134 with HCAP) and noted 35.9% (n = 71) had positive bacterial culture, 36.4% (n = 72) had viral infections, and 9.1% (n = 18) had bacterial–viral co-infections with no difference in mortality between the three groups [73]. Bacterial co-infection was more common with parainfluenza and influenza viruses and less common with respiratory syncytial virus and rhinoviruses.

When evaluating a patient with pneumonia, it is important to understand the status of each individual’s respiratory host defense system to predict which possible pathogen is most likely (Table 181.4). Thus, CAP in a previously healthy person is most likely due to a pathogen of such intrinsic virulence that it can overcome even an intact host defense system. These pathogens include *S. pneumoniae*, *Legionella* sp., *S. aureus*, viruses, and *M. pneumoniae*. If the patient has a serious underlying illness, then organisms of less intrinsic virulence that would ordinarily be eliminated by a normal host can be responsible. When an alcoholic has pneumonia, anaerobes and *Klebsiella pneumoniae* become more likely; those with chronic bronchitis may be infected with nontypeable *H. influenzae* and *Moraxella catarrhalis*; cardiac patients commonly have pneumococcal infection; those with cystic fibrosis are commonly infected by *S. aureus* and *P. aeruginosa*; and those with risk factors for aspiration can have enteric Gram-negative bacterial or anaerobic lung infection. Other associations are listed in Table 181.4. Certain historical information can be valuable, such as an appropriate travel or exposure history that suggests specific etiologic pathogens (Table 181.5).

TABLE 181.5 Historical and Physical Features Useful in Pneumonia Diagnosis
Nosocomial Pneumonia

Both VAP and HCAP may be caused by a variety of Gram-positive and Gram-negative bacteria, many of which are MDR. These infections may be polymicrobial and are seen more often among patients with ARDS than among other ventilated patients [74]. Viral or fungal pathogens are rarely causative for immunocompetent hosts [75]. Among patients who have a prolonged hospital stay, therapy with corticosteroids or antibiotics, need for long-term mechanical ventilation, and in those with ARDS, the pathogen most likely to cause pneumonia is *P. aeruginosa*, but at many hospitals, *Acinetobacter* is becoming an increasing concern. Contamination with *Legionella* sp. in the water system can lead to infection, especially among patients treated with corticosteroids. Another pathogen that should be considered when NP arises in the setting of corticosteroid therapy for COPD is *Aspergillus* sp. [76].

In the National Nosocomial Infections Surveillance (NNIS) system data examining changes in the organisms from 1986 to 2003, Gram-negative aerobes persisted as being the most frequent organisms in HAP (65.9%), with little change in their distribution over this period, except for a rise in the proportion of *Acinetobacter* from 1.5% in 1975 to 6.9% in 2003 [77]. The most common Gram-negative organism reported was *Pseudomonas aeruginosa* (18.1%), and others included *Klebsiella* spp. (7.2%), *Acinetobacter* spp. (6.9%), and *Escherichia coli* (5%). The Gram-positive organisms included *S. aureus* (27.8%), *Enterobacter* spp. (10%), coagulase-negative *Staphylococcus* (1.8%), and *Enterococci* (1.3%) [77]. This pattern was similar to a recent antimicrobial surveillance program from 1997 to 2008 of hospitalized patients with pneumonia from North
America, Europe, and Latin America—the SENTRY surveillance data [78]. In that study, *P. aeruginosa* (26.6%) and *Acinetobacter* species were more common among VAP than HAP patients. The EPIC study was a point prevalence evaluation of infection and the etiologic pathogens, in ICUs throughout the world, on a given day in 2007 and among 13,796 patients, 64% had respiratory tract infections and among all infections, Gram-negatives were more common than Gram-positives (62.2% vs. 46.8%) [79]. The most common organisms were *P. aeruginosa* and *S. aureus* (half of which was methicillin-resistant). Some studies have compared the bacteriology of pneumonia among ventilated and nonventilated patients. In one study, investigators evaluated NP over a 3-year period in ventilated (n = 164) and nonventilated patients (n = 151), finding no significant difference in the relative proportion of etiologic pathogens isolated from both the groups, except for *S. pneumoniae*, which was more common in nonventilated ICU patients than VAP patients [80]. However, another prospective surveillance study comparing 327 episodes of VAP in 309 patients with 261 episodes of HAP among 247 patients, the patients with VAP had more episodes of Gram-negative bacilli, compared to patients with HAP (59% vs. 39.6%, *p* < 0.001) and HAP patients had a higher incidence of *S. pneumoniae* and viruses [81].

HAP involving anaerobic organisms may follow aspiration among nonintubated patients but is rare among patients with VAP [4]. Gram-negative organisms are more common with aspiration, especially in the health care environment, including the nursing home [68]. Oropharyngeal commensals such as viridans group streptococci, coagulase-negative staphylococci, *Neisseria* species, and *Corynebacterium* species can produce infection of immunocompromised hosts and some immunocompetent patients. The identity of specific MDR pathogens causing HAP varies from one ICU to another, and depends on the patient population treated and the degree of prior antibiotic exposure, but the dominant organisms change over time [4,77]. Risk factors for infection with MDR pathogens are summarized in Table 181.2.

The bacteriology of HCAP is widely variable depending on the types of patients evaluated. Current data show that HCAP is a heterogeneous disease, including a wide range of patients, some severely ill and others not. In the severely ill population, often treated in the ICU, MDR Gram-negatives, and MRSA are common and must be considered when designing empiric therapy. Elderly residents of long-term care facilities have been found to have a spectrum of pathogens similar to late-onset HAP and VAP [4,82]. In patients aged 75 years and older with severe pneumonia, El-Solh et al. found *S. aureus* (29%), enteric Gram-negative rods (15%), *S. pneumoniae* (9%), and *Pseudomonas* species (4%) as the most frequent causes of nursing home–acquired pneumonia [75]. These
resistant organisms are a particular concern for severely ill patients with other risk factors, including poor functional status, prior antibiotic therapy, immune-suppressive therapy, and a history of recent hospitalization.
CLINICAL FEATURES OF PNEUMONIA

General Features of Community-Acquired Pneumonia

The signs and symptoms of pneumonia depend on both host and bacterial factors, and in the past, the presentation was classified as being either “typical” or “atypical,” but studies have shown that this approach is not clinically useful [5]. The common clinical features of CAP include fever, cough, sputum production, dyspnea, and occasionally pleuritic chest pain. Gastrointestinal symptoms that may be seen include nausea, vomiting, and diarrhea. Because many of the symptoms of pneumonia result from the host inflammatory response, patients who have altered immune function have less dramatic symptoms. Thus, those with advanced age, chronic lung disease, cardiac disease, renal failure, diabetes, immunosuppressive therapy, and other chronic illnesses have not only an increased incidence of pneumonia but also a less distinct and subtler clinical presentation. In the elderly patient, pneumonia can have a nonrespiratory presentation with symptoms of confusion, falling, failure to thrive, altered functional capacity, or deterioration in a preexisting medical illness, such as CHF.

General Features of Nosocomial Pneumonia

A major controversy is how to determine when hospital-acquired (particularly ventilator-associated) pneumonia is present. On clinical grounds alone, the diagnosis is imprecise and in the presence of diseases such as ARDS, atelectasis, pulmonary embolism, lung contusion, and CHF, all of which may be associated with lung infiltrates, pneumonia may be overlooked, or these processes may be incorrectly diagnosed as lung infection. In addition, the elderly and immunosuppressed may have few clinical findings when pneumonia develops in the hospital. Limited sputum production due to impaired immunologic status and mobilization of leukocytes compound the difficulties of diagnosis. Conversely, those on a mechanical ventilator with VAT may have purulent sputum, fever, and pathogens colonizing the sputum but not have invasive parenchymal lung infection.

Fagon et al. using quantitative cultures collected with a protected specimen brush (PSB) to define this infection for mechanically ventilated patients, have reported that up to two-thirds of cases that are diagnosed based on clinical criteria alone are not truly pneumonia [83]. Most clinical definitions of NP require the patient to be hospitalized 48 to 72 hours before the onset of purulent sputum, leukocytosis, fever, and a new
and persistent infiltrate. If these features exist along with isolation of a potential pathogen from the sputum, then this organism is deemed to be responsible for the infection. The findings of a positive blood culture or radiographic cavitation add to the likelihood of pneumonia being present. Positive blood cultures when NP is suspected can support the diagnosis, but if the organism present in the blood culture is different from the one in the respiratory tract, the bacteremia may be secondary to an extra-pulmonary infection [4]. One approach to the clinical definition of VAP, developed by Pugin et al. [84], has been to use a scoring system that weighs six clinical variables: fever, white blood cell count and differential, the presence of pathogens in the sputum, sputum purulence, radiographic patterns, and oxygenation changes. When this Clinical Pulmonary Infection Score (CPIS) has been used, the clinical and quantitative bacteriologic definitions of pneumonia have correlated very well.

The CDC definition of VAP is subject to significant interobserver variability. Klompas and associates developed a simplified streamlined surveillance definition of VAP excluding the criteria of delirium and rales, and defined worsening oxygenation as at least 2 days of stable or decreasing daily minimum PEEP, followed by an increase of at least 2.5 cm H₂O of PEEP for more than 2 days; or at least 2 days of stable or decreasing fraction of inspired oxygen (FiO₂), followed by a sustained increase of at least 0.15 in FiO₂ over 2 days [85]. Compared to the conventional definition, the streamlined definition identified patients with VAP faster (3.5 vs. 39 minute per patient) and more objectively, with no major difference in hospital mortality, ICU length of stay, and ventilator days between the two definitions. More recently, hospitals have begun to look at a new condition, ventilator-associated complications (VAC), which relies heavily on changes in oxygenation, and is related to pneumonia, but includes a number of other illnesses, as discussed below.

The use of biomarkers, both in the serum and in the respiratory secretions, may help in making this difficult diagnosis. For patients with VAP, studies have used PCT, C-reactive protein, soluble triggering receptors expressed on myeloid 1 (STREM), and IL-6, among others [86–88]. Ramirez and colleagues found that a combination of CPIS of at least 6 points and serum PCT levels of at least 2.99 ng per mL had 100% specificity and negative predictive value of 92% (AUC = 0.961) for the diagnosis of VAP [89]. In another prospective study, serial PCT measurements on days 1, 3, and 7 were significantly higher among
microbiologically proven VAP patients who had an unfavorable outcome than those with a favorable outcome, while serial CPIS values were less discriminatory [90]. The difficulty to accurately diagnose NP, especially VAP in the absence of a gold standard test, is a concern, and clinicians often start broad-spectrum antibiotics based on clinical judgment.
DIAGNOSTIC APPROACH TO THE PATIENT WITH SEVERE PNEUMONIA

Once the presence of severe pneumonia has been defined, the patient should be categorized by place of origin of infection, defining the illness as CAP, HCAP, or HAP (including VAP). Then the immune competence of the patient, the types of comorbid diseases present, and the existence of risk factors for specific pathogens should be defined to identify the most likely etiologic pathogens. Historical data, physical examination, and laboratory findings pertinent to diagnoses will also be helpful for determining which etiologic agent is responsible and what specific therapy should be instituted (see Tables 181.4 and 181.5). For example, contact with animals, especially birds, rats, and rabbits, can suggest the diagnosis of psittacosis, plague, and tularemia, respectively.

Historical Information

The history can be used to determine if the patient has pneumonia as the cause of his or her acute illness, recognizing that certain populations, such as the elderly, may have an altered, nonclassical presentation. Among elderly and compromised hosts, the infection may be heralded only by lethargy and confusion [69]. Among compromised hosts with malignancy or immunosuppressive therapy, the presentation may be so stunted that pneumonia may only be discovered only at autopsy.

Hemoptysis is an important historical feature, since it implies tissue necrosis and is most common with pyogenetic streptococcal pneumonia (groups A to D), anaerobic lung abscess, *S. aureus*, necrotizing Gram-negative organisms, and invasive aspergillosis. Microaspiration of anaerobic organisms leading to pneumonia is more likely with a history of preexisting severe periodontal disease or with a history of seizure disorder, altered consciousness, or esophageal obstructive disease. Extrapulmonary symptoms may give clues to specific etiologic agents, with diarrhea and abdominal discomfort being seen in patients with *Legionella* sp. and otitis media and pharyngitis with *M. pneumoniae* (Table 181.6).

For the patient with NP, the history should focus on whether the patient has recently received antibiotics and how long the patient has been in the hospital prior to the onset of infection. Both are risk factors for infection with MDR Gram-positive and Gram-negative bacteria. In addition, the specific antibiotics used in the past 2 weeks should be recorded, since the pathogens causing the current infection are likely to be resistant to those agents. Other risk factors for MDR pathogens that can be present in those with HAP and HCAP include hospitalization in the past 90 days, poor functional status, and immunosuppressive therapy (including corticosteroid use).

### Physical Examination

The physical examination is valuable for suggesting the presence of pneumonia and for grading its severity. Tachypnea (>20 breaths per minute) may be the earliest sign of pneumonia among the elderly, and findings of consolidation are more specific for pneumonia than crackles, especially in the ICU [91]. In patients with CAP, an admission respiratory rate greater than 30 breaths per minute is an important negative prognostic feature, and in some studies mortality increases dramatically
when respiratory rate exceeds this level [92]. Signs of pleural effusion are particularly common with \textit{H. influenzae}, pneumococcal, streptococcal, and aspergillus pneumonia, where pleural friction rubs may be detected. Pleural involvement can be seen, although less often, in \textit{Legionella} and \textit{M. pneumonia}. Relative bradycardia is a frequent finding in many pneumonias caused by \textit{Mycoplasma}, \textit{Legionella}, and \textit{Chlamydophila} organisms [93].

Dermatologic manifestations (erythema nodosum, erythema multiforme, and skin nodules) may be observed with \textit{Mycoplasma}, fungal, \textit{Nocardia}, and tuberculous infections. Horder spots (pale macular rash), long considered part of the presentation of psittacosis, should lead the clinician to look for other evidence of this infection. Ecthyma gangrenosum, an indurated, round skin lesion with a central dark area surrounded by erythema, is characteristic of Gram-negative septicemia, especially with \textit{P. aeruginosa}. Central nervous system abnormalities can be found in infections with pneumococcus, \textit{M. tuberculosis}, \textit{H. influenzae}, Gram-negative organisms, cryptococci, \textit{Aspergillus} sp., \textit{Legionella} sp., \textit{Toxoplasma gondii}, varicella zoster, and cytomegalovirus (CMV). Other physical findings that narrow the differential diagnosis include splenomegaly in the case of psittacosis and tularemia, herpes labialis in pneumococcal infection, bullous myringitis with \textit{M. pneumoniae} infection, and lymphadenopathy with tularemia. The predictive value of many of these observations has not been evaluated rigorously (Table 181.6).

**Routine Diagnostic Testing**

The IDSA/ATS guidelines for CAP recommend a relatively streamlined evaluation, including chest radiograph, routine blood chemistries and blood counts, blood cultures (for the critically ill), assessment of oxygenation (oximetry or blood gas), and a clinical evaluation of severity of illness. Although the routine use of sputum culture or Gram stain of sputum is not recommended, these tests should be done for critically ill patients to identify unusual or drug-resistant organisms. If a sputum sample is obtained, it should be prior to therapy, rapidly transported to the lab, and of good quality with little evidence of oral contamination. The critically ill, intubated patient should have an endotracheal aspirate sent for culture, and \textit{Legionella} and pneumococcal urinary antigen testing should be considered. The routine use of serologic testing is not encouraged [5]. The impact of diagnostic testing for patients with severe
CAP remains uncertain, and several studies have shown that even when the etiologic diagnosis is known, outcome may not be affected, whereas the use of early and effective empirical therapy has been associated with improved outcomes [5,40]. However, Rello et al. have shown that knowing the etiologic pathogen can help to focus and simplify treatment in nearly one-third of cases of severe CAP [93].

Most routine laboratory results are not specific for individual pathogens, and the focus of diagnostic testing is to assess disease severity. Extremes of white blood cell count (<4,000 or >30,000 per μL) may indicate overwhelming sepsis and may be a poor prognostic finding [5]. Elevated liver function tests are not a specific finding but can be seen in a variety of viral and bacterial pneumonias, including those associated with Legionella sp., M. tuberculosis, Mycoplasma sp., Q fever, tularemia, and psittacosis, as well as in pneumococcal infection. Similarly, electrolyte disturbances, including hypophosphatemia and hyponatremia, are not predictive of a specific pathogen for the individual patient with pneumonia, but hyponatremia (<130 mEq per L) on admission may predict a poor outcome [94].

Serology, Urinary Antigen, and PCR Testing

As mentioned, routine serologic testing is not recommended because results are rarely positive at the time of presentation (i.e., convalescent serologic testing is usually needed), and even if positive, results are usually not available during the first 24 to 48 hours of critical illness [5]. Serologic responses are useful for retrospective epidemiologic purposes to document viral and so-called atypical pathogen infection and may be useful if the patient is not responding to appropriate empiric therapy (discussed later). Many patients with CAP have serologic evidence for recent atypical pathogen infection, but in the setting of an illness like Legionella pneumonia, convalescent titers are essential and less than 10% of those with acute illness have a positive serologic result. To make the diagnosis of Legionella pneumonia acutely, urinary antigen testing has the highest yield (approximately 50%), but is specific for serogroup I infection [5]. The direct immunofluorescent stain of sputum for L. pneumophila has a sensitivity of between 25% and 50% and a specificity of more than 90% for this organism. The urinary antigen for the detection of pneumococcal pneumonia has also been described for patients with severe disease, asplenia, liver disease, alcoholism, or leukopenia. Genetic probes for specific viral DNA and RNA are available for CMV, varicella zoster, herpes simplex, influenza virus, and adenovirus.

Chest Radiographic Interpretation
The chest radiograph is essential for the diagnosis of pneumonia for the critically ill patient (Table 181.7), and the use of pattern reading can help to narrow the differential diagnosis of CAP and HAP, particularly when used in concert with other available information. For example, the rapid development of a diffuse alveolar pattern frequently implies a hematogenously disseminated infection such as varicella or CMV, or the development of ARDS as a pneumonic complication. Hyperinflation is characteristic of respiratory syncytial virus pneumonia. A more subacute presentation of diffuse alveolar infiltrates may represent hematogenous dissemination of tuberculosis. *P. jiroveci* must be considered in the setting of a diffuse alveolar or reticulonodular pattern for groups at risk for HIV infection. Noninfectious causes of pulmonary infiltrates such as heart failure, bronchiolitis obliterans and organizing pneumonia (BOOP), drug toxicity, and lymphangitic carcinomatosis can also have this presentation. Focal infiltrates (i.e., confined to single segments or lobes) are most likely to represent bacterial pneumonia related to microaspiration into a particular area of the lung.

Acute bacterial pneumonias generally progress more rapidly (hours to days) than fungal or mycobacterial infections (days to weeks). Pleural effusions occur commonly in *H.* *influenzae* pneumonia (>50%) and pneumococcal infection (25%) but can also be seen in patients with group A streptococcal pneumonia. Cavitation can occur in both infectious and noninfectious lung disease, but the finding of multiple cavitary nodules suggests septic embolization from right-sided endocarditis. Rapid cavitation is also common among Gram-negative pneumonias, whereas a subacute course with cavitation suggests anaerobic or mycobacterial infection. Cavitation and necrotizing pneumonia also are present in CA-MRSA pneumonia, and its presence is often used to guide initial empirical antibiotic treatment. Occasionally, ventilator-associated bacterial pneumonia can progress rapidly and fatally, emphasizing the need for timely recognition and therapy. Chronic cavitation (weeks to months) is more likely due to a noninfectious problem, such as carcinoma, lymphoma, or granulomatosis with polyangiitis (Wegener granulomatosis), especially in the absence of the systemic signs of acute infection.

The limitations of the chest radiograph for critically ill patients are considerable, especially for the detection of VAP, when the clinician must rely on a portable film, which may not show findings very clearly. Also, among ICU patients, coexisting and preexisting lung disease may obscure the findings of pneumonia. Chest radiographs are of limited value for predicting the causative pathogen of CAP, but are useful for determining the extent of pneumonia and detecting complications such as parapneumonic effusions [95]. CT scans of the chest generally have a higher sensitivity for diagnosing occult pneumonia, with an initially negative chest radiograph [96].

Sputum Examination and Evaluation of Other Respiratory Secretions

Although Gram stain of the sputum has been the traditional first step for the evaluation of patients with suspected pneumonia, this is problematic for the critically ill patient who is not intubated and may be unable to expectorate. When a specimen is obtained from a nonintubated patient, the sample should have more than 25 polymorphonuclear cells and less than 10 epithelial cells per low-power field. When such criteria are met and intracellular organisms are identified, a bacterial density above $10^5$ colony-forming units per mL of secretions is usually present [5]. In
In addition to not always being able to distinguish airway colonization from pneumonia, the sputum Gram stain may be falsely negative up to 50% of the time compared with blood cultures. Some findings from the sputum may suggest specific etiologies. For example, an inflammatory Gram stain (polymorphonuclear cells) without organisms in a patient with pneumonia is presumptive evidence of an atypical (Legionella or Mycoplasma) or viral cause. Gram stain may be best used to broaden initial empirical therapy, rather than to narrow it, especially if an unusual pathogen that is not routinely treated is thought to be present. For example, the finding of Gram-positive cocci in clusters in a patient with influenza would lead to empiric therapy for S. aureus. The use of special stains for tuberculosis and silver or staining for P. jiroveci may provide definitive evidence for these organisms. With the use of rapid point-of-care diagnostic tests for influenza virus, treatment and chemoprevention can be offered. Rapid influenza testing can sometimes differentiate influenza A from influenza B and this can guide treatment decision. Other diseases caused by agents of bioterrorism and endemic diseases can be identified by examination of respiratory secretions.

Cultures

A definitive etiologic diagnosis of pneumonia can be made when cultures of blood, pleural fluid, or spinal fluid are positive in the presence of a lung infiltrate and a compatible clinical picture. Bacteremia is uncommon for most pneumonias, occurring among less than 15% of patients with CAP, in 20% of pneumococcal infections, and in only 8% to 15% of NPs [97]. For CAP initial PCT levels on admission may predict risk for bacteremia with levels of <0.25 mg per L identifying patients at very low risk for bacteremic episodes [98]. In a study including 3,786 patients from two large prospective studies, predictors of bacteremia with CAP were found to be younger age, high C-reactive protein, leukocytosis or leukopenia, low platelet count, low sodium level, elevated urea, and elevated arterial pH [99]. Among those with NP, the presence of bacteremia may imply an extrapulmonary infection, especially when the organism presents in the blood culture is different from the one in the respiratory tract. Blood cultures are indicated for all patients admitted to the ICU with a diagnosis of pneumonia but are most valuable if collected prior to antibiotic therapy [100].

Sputum cultures can be difficult to interpret because of the problem of separating infection from colonization among the critically ill. In a study of bacteremic NP, sputum culture yielded both false-positive and false-negative findings compared with blood cultures, with only 49% of the cases having the same organism recovered from both blood and sputum [97]. Among intubated patients, colonization is present after several days,
so the culture should be interpreted in the clinical context of the patient, and a sample should not be cultured in the absence of clinical signs of infection. Viruses may be cultured from respiratory secretions, but this procedure may take up to 20 days, depending on the virus. Thus, cytologic evidence of viral infection that can be recognized sooner may provide helpful information. For example, inclusion bodies and multinucleated giant cells are suggestive of CMV or herpesvirus infection.

**Invasive Diagnostic Sampling and Quantitative Cultures**

Because of the inherent problems distinguishing colonizing from infecting pathogens in samples of lower respiratory tract secretions, investigators have advocated for the collection of deep respiratory secretions through invasive (bronchoscopic) or semi-invasive (catheter-lavage) means, combined with analysis of the results using quantitative cultures. Bronchoscopic sampling has been used for the critically ill, particularly among those who are immunosuppressed or who already have an endotracheal tube in place, such as patients with VAP and severe CAP. Cultures are obtained by using the bronchoscopically directed PSB, or bronchoalveolar lavage (BAL), and the samples cultured quantitatively. When PSB samples are cultured quantitatively, patients with NP will have greater than $10^3$ organisms per mL of respiratory secretions. When BAL is used, a threshold concentration of $10^4$ to $10^5$ organisms per mL is used to define pneumonia [4]. In some studies, lower airway cells recovered by lavage have been examined for the presence of intracellular organisms, and the finding of more than 5% to 25% of cells with intracellular bacteria may predict the diagnosis of pneumonia, confirmed by PSB. Quantitative endotracheal aspirates have also been used, particularly for patients with severe nursing home pneumonia, and this technique has a very good correlation with results of BAL when a threshold of $10^4$ colony-forming organisms per mL is used [4,101]. Although the role of bronchoscopy for patients with suspected VAP is still controversial, most investigators agree that BAL is valuable for establishing a nonbacterial cause of infection, especially for the immunocompromised host or the patient with HIV infection, where it can reliably diagnose *P. jiroveci* pneumonia and CMV infection [102].

Quantitative cultures have been proposed as the most accurate way to establish the presence of VAP and to define the etiologic pathogen. Although the clinical diagnosis of VAP has been much maligned, it may be very accurate, particularly when it is objectively defined by calculating
the CPIS and if the score incorporates a Gram stain of a lower respiratory tract sample [103]. Once the clinical diagnosis of VAP is made, a culture is needed to identify the etiologic pathogen, but this culture could be quantitative or semiquantitative (light, moderate, or heavy growth), and collected as an endotracheal aspirate or via bronchoscopy or catheter lavage. Studies of the impact of quantitative culture methods on VAP outcome have been mixed, but a meta-analysis showed no effect on mortality [104]. Singh et al. used clinical diagnosis and management with the CPIS and showed that patients with suspected VAP and a low score could be safely managed with a short course of antibiotics [105]. In a large multicenter trial, Heyland et al. compared management of VAP using cultures obtained via endotracheal aspirates with those obtained by BAL [106]. They found no difference of mortality between the two groups, and similar rates of adjusting antibiotic therapy after initial empiric management. Unlike an earlier study, in this investigation, all patients initially received antibiotic therapy, so cultures were used to adjust antibiotics but never to withhold them. One of the limitations of these data is that less than 15% had MDR pathogen pneumonia. A recent systematic review using Cochrane Database including five randomized controlled trials with 1367 VAP patients, comparing quantitative microbiologic sample to qualitative sampling found no differences of mortality, ICU length of stay, or higher rates of antibiotic change between the two groups [107]. Fewer studies have been done to investigate the impact of quantitative lower respiratory secretion cultures for patients with severe CAP. Rello et al. have shown that information from bronchoscopic sampling can help to narrow and focus antibiotic therapy for patients with severe CAP [93]. However, among patients with severe CAP, PSB and BAL only give an etiologic diagnosis in one-quarter to one-third of all patients (which is less than with sputum or endotracheal aspirate cultures), but among this group, antibiotics were changed in nearly 75%.

Guidelines for NP have recommended that all patients have a lower respiratory tract sample collected prior to starting therapy, and that the technique and culture method should be one that the clinician is expert at performing and interpreting. Lower respiratory tract cultures can be obtained bronchoscopically or nonbronchoscopically and can be cultured quantitatively or semiquantitatively. Quantitative cultures increase specificity of the diagnosis of HAP but may potentially delay the initiation of therapy for patients with early pneumonia. Nonquantitative cultures are sensitive but may lead to some colonizing organisms being treated. Regardless of which method is used, it should only be initiated once the clinician has made a clinical diagnosis of pneumonia and is ready to initiate therapy. Therapy should be prompt and not delayed for the purpose of collecting a diagnostic sample, especially for patients who are
clinically unstable or septic from pneumonia [4].

Percutaneous needle aspiration of the lung in an area of infiltrate has also been studied, but it is limited by a high incidence of false-negative results and an unacceptable complication rates, including pneumothorax in up to 30% of patients and a 10% rate of hemoptysis. Although open lung biopsy is the unequivocal standard for the diagnosis of infection, it has been applied primarily for the immunocompromised host with rapidly advancing, life-threatening infection. Aspergillus, CMV, herpes simplex, and T. gondii infections are more readily diagnosed by open lung biopsy than by other described techniques. For patients with CAP, open lung biopsy is rarely needed, and its potential for demonstrating a treatable infection that will alter outcome is low, and similar findings have been reported when it is used in patients with HAP [108] (Table 181.8).

<td>“Invasive”; requires special training; less useful if patient already on antibiotics; wide range of sensitivity; may bias against the treatment of early infection</td>
</tr>
</tbody>
</table>
Nonbronchoscopic BAL
May give quantitative culture data in ventilated patients; can be done any time of the day by respiratory therapists or physicians
Variable accuracy, assumes that random sampling is reflective of bacteriology throughout the lung; same benefits/disadvantages of relying on other quantitative methods

Open lung biopsy
Excellent for nonbacterial diagnosis and in compromised host
Most invasive; critically ill may not be able to undergo procedure; may not change prognosis

Lung Ultrasound (LUS)
Bedside, noninvasive, real time echography of the lung is increasingly being adopted by intensivists for diagnosing pleural and pulmonary diseases. Various patterns with B and M mode ultrasound techniques including—“tissue sign” and “dynamic airbronchograms” are seen with pulmonary consolidation. (The utility of lung ultrasound for diagnosis of pneumonia is reviewed in Chapter 11.) Multiple studies have compared LUS to CT chest and the sensitivity and specificity ranges from 90% to 100% [109]. Reissig and associates in a prospective, multicenter study, including 362 patients with suspected CAP found LUS to have a sensitivity of 93.4% and specificity of 97.7% compared to chest X-ray and CT chest [110]. In another study, investigators proposed a new score for diagnosing VAP using PCT level and chest echography: the Chest Echography and Procalcitonin Pulmonary Infection Score (CEPPIS) [111]. In that study, a CEPPIS >5 performed better than CPS >6 for diagnosing VAP (OR, 23.78; sensitivity, 80.5%; specificity, 85.2%) [111]. Although LUS is operator dependent, a recent meta-analysis of 10 studies with 1,172 patients supports the use of LUS by skilled practitioners [112].

Ventilator Associated Events
A CDC working group has proposed monitoring for a new entity, ventilator associated events (VAE), in order to “objectively” measure the complications related to mechanical ventilation, as an alternative to looking for VAP, which as discussed, is difficult to define. VAE is recognized by assessing for worsening oxygenation (defined by ventilator settings and not by physiologic measurements) and systemic signs of infection [113]. VAE includes VAC, infectious ventilator-associated complications (IVAC), and probable, as well as possible VAP (Table 181.9). Muscedere et al. studied the clinical impact and preventability of
VAC and IVAC, and the relationship to VAP, using prospectively collected data from 1,320 patients [114]. They found VAC developed in 10.5% and patients who had VAC were more likely to develop VAP than those who did not (28.1% vs. 9.2%, \( p < 0.001 \)). However, only 39 of 139 with VAC had VAP, and most patients with VAP did not have VAC or IVAC. When prevention efforts were undertaken, they were able to reduce the incidence of VAC and VAP, but not IVAC. In another study, patients with VAC had a higher ICU length of stay (22 vs. 11 days), duration of mechanical ventilation (20 vs. 5 days), and use of antibiotics than non-VAC patients, but no difference of overall ICU mortality [115]. VAC definitions were not specific for VAP and included atelectasis in 16.3%, acute pulmonary edema in 11.8%, and acute respiratory distress syndrome in 6.5%. Thus the VAC definition identified sick patients, but not all VAC patients had pneumonia. In a recent study only 32% of patients with VAP identified by prospective surveillance were detected using the VAE algorithm [116]. Bouadma and associates analyzed a large prospective cohort of ventilated patients, and found a significant correlation between VAP and IVAC episodes [117]. Although the VAE definitions track episodes of sustained respiratory deterioration among mechanically ventilated patients after a period of stability or improvement, VAC and IVAC are not always VAP, and the prevention efforts for VAP do not always affect VAC and IVAC rates, raising doubt about the utility of these new definitions as a measure of the quality of care for ventilated patients [118].

Probable VAP

On or after calendar day 3 of mechanical ventilation and within 2 calendar days before or after the onset of worsening oxygenation, ONE of the following criteria is met:

1. Purulent respiratory secretions (from one or more specimen collections—and defined as for possible VAP) AND one of the following: Positive culture of endotracheal aspirate, ≥10⁵ CFU/mL or equivalent semiquantitative result, or positive culture of bronchoalveolar lavage, ≥10⁴ CFU/mL or equivalent semiquantitative result, or positive culture of lung tissue, ≥10⁴ CFU/mL or equivalent semiquantitative result, or positive culture of protected specimen brush, ≥10³ CFU/mL or equivalent semiquantitative result.

2. One of the following (without requirement for purulent respiratory secretions): positive pleural fluid culture (where specimen was obtained during thoracentesis or initial placement of chest tube and NOT from an indwelling chest tube), or positive lung histopathology, or positive diagnostic test for Legionella spp., or positive diagnostic test on respiratory secretions for influenza virus, respiratory syncytial virus, adenovirus, and parainfluenza virus.

Differential Diagnosis

In the evaluation of a patient with lung infiltrates, it is necessary to determine (a) if it is pneumonia, or another infiltrative or inflammatory
process, that is responsible for the constellation of symptoms and signs being evaluated and (b) if it is pneumonia, what is the etiologic pathogen. Since the features of pneumonia are nonspecific, it is necessary to consider such alternative noninfectious processes such as aspiration with chemical pneumonitis, acute pulmonary embolism, pulmonary infarction, pulmonary hemorrhage, ARDS, CHF, BOOP, radiation pneumonitis, bronchoalveolar carcinoma, and atelectasis. An increasingly common problem is the differentiation of acute infectious pneumonia from drug-induced pneumonitis caused by agents such as amiodarone, bleomycin, busulfan, methotrexate, and newer cancer treatments, such as immune checkpoint inhibitors.

Among immunocompromised patients, a new lung infiltrate may represent infection, progression of the underlying primary disease, or drug-induced lung disease. As for all patients, the nature of the immune impairment determines which pathogens are most likely. Although P. jiroveci pneumonia is a cause of rapidly progressive hypoxemic respiratory failure in the patient with HIV infection, a similar picture may be seen with tuberculosis, and pneumococcus is also a common respiratory pathogen among these patients [119]. Many have suggested that tuberculosis is poorly recognized in the intensive care setting and should be considered for patients with a history of inadequately treated tuberculosis or radiographic evidence of previous infection. The use of corticosteroid therapy in doses more than 20 mg per day increases the risk of opportunistic fungi, with reports stressing the occurrence of invasive aspergillosis among patients receiving high-dose steroid therapy for exacerbations of COPD. Patients with impaired B-cell function such as multiple myeloma are particularly prone to pneumonia with encapsulated organisms, including pneumococcus and H. influenzae. A similar organism profile can be seen among splenectomized patients and among those with complement defects. Even in the setting of established pneumonia, patients may have a second infectious process such as extrapulmonary infection (catheter-associated bacteremia) or complications of antibiotic therapy, such as antibiotic-induced colitis.
Supportive Therapies

Supportive therapies for pneumonia in the critically ill are crucial, because the use of antibiotics may not impact the course of disease during the first 24 to 72 hours of treatment. Many of the commonly applied measures are based on traditional practice, with little documentation of efficacy.

Nutritional Support

Evidence implicating malnutrition as a cofactor for pneumonia is substantial, but the evidence that nutritional intervention alters the outcome of severe pneumonia is lacking [69]. Enteral nutrition is preferred, if this can be practically accomplished, because data suggest better preservation of immune function using this route compared with total parenteral nutrition [120]. When enteral feedings are given, a small-bore tube, preferably placed in the small bowel, should be used along with a continuous infusion method to prevent aspiration and to optimize the delivery of calories [121]. All patients should be kept semierect (greater than 30 degrees upright) and not supine as much as possible, to reduce the risk of reflux and aspiration [58]. The optimal time for initiating enteral feeding has not been determined.

Chest Physiotherapy

There is little support for the routine application of chest physiotherapy in patients who have an effective cough and scant amounts of respiratory secretions. Because of the labor-intensive nature of this intervention, techniques such as percussion, vibration, and postural drainage should be specifically targeted to patients with large volumes of purulent secretions (>30 mL per day) and an ineffective clearance by coughing. For patients at bed rest in the ICU, the use of positioning and rotation may be helpful for clearing secretions. In several studies, particularly of surgical trauma patients, the preventive use of beds that rotate patients from side to side, and presumably accelerate mucus clearance, has led to a reduced incidence of NP [122].

Aerosols and Humidification

Humidification has been a traditional practice of respiratory therapy
aimed at reducing sputum viscosity and promoting mucociliary clearance. Because the deposition of water vapor depends on particle size and the degree of airway obstruction, it is likely that most aerosols are deposited above the glottis and act only to stimulate cough. Although mucolytic agents such as acetylcysteine offer the theoretic benefit of reducing the viscosity of purulent secretions, they may act as irritants that can provoke bronchospasm, and thus must be used selectively. Bronchodilator therapy with $\beta_2$ agents can enhance mucociliary clearance and ciliary beat frequency, but there have been no controlled trials that have demonstrated improved outcomes with their use for pneumonia, in the absence of underlying bronchospasm. The greatest benefit of bronchodilator therapy may be expected in the patient with COPD in whom pneumonia develops.

**Antibiotic and Other Pharmacologic Therapies**

Among the critically ill, timely initiation of appropriate antimicrobial therapy has been shown to improve survival for patients with both severe CAP and VAP [4,5,42]. Because it is often impossible to identify a specific etiologic agent at the time that therapy is started, initial therapy is necessarily empirical but can be modified and focused (de-escalated) once the results of diagnostic testing become available. The ATS and IDSA have developed algorithms for initial empiric therapies of severe pneumonia arising in both the community and the hospital.

**Community-Acquired Pneumonia**

Because the use of clinical syndromes or sputum Gram stain to guide therapy is often inaccurate and not recommended, initial therapy is empirical, based on the likely etiologic pathogens. For patients treated in the ICU, monotherapy is not recommended, regardless of agent, all patients require initial therapy directed at pneumococcus (including DRSP), atypical pathogens (especially *Legionella*), *H. influenzae*, and enteric Gram-negatives (including *P. aeruginosa* for some patients). For selected patients, particularly following influenza or other viral infections, empirical therapy for *S. aureus*, including MRSA, may be necessary. Aspiration pneumonia, including anaerobic pathogens, can occasionally present as severe illness, needing ICU care. Endemic viruses can also cause severe CAP, and the use of antiviral agents depends on local epidemiology and whether influenza or another viral agent is suggested by rapid testing or is prevalent at the time that the patient is being evaluated. Among the critically ill, initial therapy is determined by whether the patient has risks for *P. aeruginosa*, which include structural lung disease (bronchiectasis), therapy with broad-spectrum antibiotics...
for more than 7 days in the last month, use of corticosteroids (>10 mg of prednisone daily), malnutrition, or HIV infection [5].

For the patient with severe CAP, mixed infection, involving a bacterial pathogen and an atypical pathogen, is also common and should be covered by the initial empiric regimen. Every patient should receive therapy directed at these organisms, which can be either as a primary pathogen or copathogen, but studies have shown that the use of a macrolide may be of specific value. In patients with bacteremic pneumococcal pneumonia, particularly in those with severe illness, dual therapy including a macrolide has been associated with improved outcomes [123,124]. A quinolone can also be used to treat atypical pathogen infection and may have an advantage for the patient with suspected Legionella infection, where the outcomes using quinolones have been exceptionally good [125].

When the patient has no risk factors for Pseudomonas, therapy should be with an intravenous β-lactam (ceftriaxone or cefotaxime) with activity against DRSP plus either intravenous azithromycin or an intravenous quinolone (levofloxacin 750 mg or moxifloxacin 400 mg). When the patient has risk factors for Pseudomonas, therapy should involve two antipseudomonal agents, in addition to providing coverage for DRSP and Legionella [5]. For these patients, therapy can be a two-drug regimen, using a selected antipseudomonal β-lactam (cefepime, piperacillin/tazobactam, imipenem, and meropenem), in combination with an antipseudomonal quinolone (ciprofloxacin, high-dose levofloxacin 750 mg daily). Alternatively, the above-mentioned β-lactams can be combined with an aminoglycoside and either azithromycin or an antipneumococcal quinolone (levofloxacin 750 mg or moxifloxacin 400 mg). For the penicillin-allergic patient, aminoglycoside and aztreonam can be combined with an antipseudomonal quinolone. Occasionally, these broad-empiric approaches should be modified, particularly when clinical or culture data suggest an organism that is not included in the initial regimen (e.g., S. aureus or MRSA). In addition, certain comorbidities predispose to specific pathogens, and these should be covered by the chosen empiric regimen (see Table 181.4).

In a recent cluster-randomized crossover study, Postma and colleagues compared β-lactam monotherapy (BL, n = 656), β-lactam–macrolide combination therapy (BLM, n = 739), and fluoroquinolone monotherapy (FQ, n = 889) for hospitalized non-ICU CAP patients [126]. The investigators found no difference in 90 day mortality between the three groups (BL = 9%, BLM = 11% and FQ = 8.8%), but 38.7% of patients in β-
lactam monotherapy group received an additional agent during their hospital stay for atypical coverage, which was not considered a deviation from the protocol. Adrie et al. compared the impact of dual (β-lactam plus macrolide or fluoroquinolone \([n = 394]\)) versus monotherapy (β-lactam alone \([n = 471]\)) for immunocompetent severe CAP, and there was no difference of 60-day mortality between the two groups [127]. However, there was survival advantage for patients, who had initial adequate antibiotic therapy and those who received dual therapy had a higher frequency of initial adequate antibiotics. In another report, Garin et al. found patients treated with β-lactam monotherapy were less likely to reach clinical stability compared to β-lactam–macrolide combination, if they were infected with atypical pathogens or if they had severe pneumonia with PSI category IV [128]. Sligl and colleagues conducted a meta-analysis of macrolide use for severe CAP, including 28 studies and nearly 10,000 patients [129]. They found a significant reduction of mortality from 24% to 21% \((p < 0.05)\) when a macrolide was used in this patient population.

As mentioned earlier, no patient with severe CAP should receive monotherapy, even with a quinolone, since studies have not proven the efficacy of this approach [130]. Although quinolones are acceptable as monotherapy for patients who are not critically ill, it is currently uncertain if the outcome is different when a quinolone is used in place of macrolide, as part of a combination regimen for patients in the ICU. Moxifloxacin is safe and efficacious for CAP, even for the elderly, but few patients with severe CAP have been studied with monotherapy. In the Community-Acquired Pneumonia Recovery in the Elderly (CAPRIE) study, comparing moxifloxacin with levofloxacin for CAP among the elderly who were hospitalized outside of the ICU, although the cure rate for moxifloxacin (94.7%) was greater than levofloxacin (84.6%) in the severe CAP subgroup, the difference was not statistically significant [131]. One study of nearly 400 patients with severe CAP compared monotherapy with high-dose levofloxacin (500 mg twice daily) with the combination of ceftriaxone/ofloxacin, and although an equivalent clinical response was observed in both treatment groups (79.1% with levofloxacin compared with 79.5% with combination therapy), patients with shock were excluded from the study, and among patients with mechanical ventilation, treatment with levofloxacin resulted in a lower clinical cure rate (63% compared with 72% with combination therapy) [130]. Therefore, quinolone monotherapy is not recommended for patients with severe CAP, especially in the setting of septic shock and respiratory failure.

In one report, the use of initial empiric therapy with a β-lactam plus a fluoroquinolone for severe CAP was associated with increased short-term mortality (OR, 2.71; 95% confidence interval, 1.2 to 6.1), compared to
other guideline-recommended antimicrobial regimes [132]. On the other hand, a meta-analysis of 23 randomized trials of CAP therapy outside the ICU compared the use of fluoroquinolones with other antibiotics, including β-lactams, macrolides, or both. Although there was no mortality difference in favor of the fluoroquinolones, for patients with more severe pneumonia, those who required hospitalization and those requiring intravenous therapy, the quinolones were more effective [133].

If DRSP is present, any of the recommended regimens will be effective. Although pneumococcal resistance to multiple agents is present at rates up to 40%, using older definitions of resistance, the outcome in CAP is generally not worsened by the presence of penicillin-resistant organisms, compared with penicillin-sensitive organisms, and that these resistant organisms can still be effectively treated by high doses of penicillin, amoxicillin, amoxicillin/clavulanate, the third-generation cephalosporins (ceftriaxone or cefotaxime), or the antipneumococcal fluoroquinolones [5]. If highly resistant pneumococcus (but not cephalosporin resistant) is documented and meningitis is present, therapy should be initiated with vancomycin, cefotaxime, or ceftriaxone. Discordant therapy of DRSP usually has no impact on outcomes, but even for studies when it was independently associated with death (OR, 27.3), it was very unlikely that discordant therapy would be given with ceftriaxone or cefotaxime [134]. Ceftriaxone is usually used at doses of 1 to 2 mg per day, but if DRSP and severe infection are present, the dose can be increased to 2 g every 12 hours. A notable exception to using cephalosporins for severe CAP is cefuroxime. Yu et al. [135] studied patients with bacteremic pneumococcal pneumonia, and found that discordant therapy with cefuroxime did increase mortality in the presence of in vitro resistance. H. influenzae is also becoming increasingly resistant to common antimicrobials because of the production of β-lactamases, and these organisms can be treated with second- or third-generation cephalosporins, quinolones, macrolides, or ampicillin/sulbactam. Other new antibiotics may become available for the therapy of CAP. Tigecycline is a novel glycylcycline antibacterial agent, with an expanded broad spectrum of activity including proven utility against Gram-positive, Gram-negative, anaerobic, and atypical pathogens. It is effective in vitro against clinically important community- and hospital-acquired resistant organisms—Acinetobacter, MRSA, DRSP, vancomycin-resistant Enterococcus spp., E. coli, and K. pneumoniae expressing extended-spectrum β-lactamases (ESBLs). Currently, it is approved for CAP, but not as monotherapy for NP [136]. New anti-Staphylococcal agents are also being developed, and may have utility for severe CAP, including telavancin and ceftaroline [137]. Ceftaroline fosamil is a cephalosporin approved by FDA for use in the treatment of acute bacterial skin infections and CAP [138]. Nemonoxacin is a newly developed quinolone
with broad-spectrum activity against Gram-positive, Gram-negative and atypical pathogens, including drug-resistant *S. pneumoniae* and methicillin-resistant *Staphylococcus aureus*, and is being investigated in pneumonia [139].

### Duration of Treatment

Currently there are insufficient data on the appropriate duration of treatment for critically ill CAP patients. Generally, *S. pneumoniae* can be treated for 5 to 7 days if the patient is responding rapidly and has received the correct dose of an accurate therapy. Longer duration of treatment is necessitated by the presence of extrapulmonary infection (e.g., meningitis), and the identification of certain pathogens (such as bacteremic *S. aureus* and *P. aeruginosa*). *L. pneumophila* pneumonia may require at least 14 days of therapy, although shorter duration therapy has been effective using quinolones. Antibiotics can be switched from intravenous to oral once the patient is afebrile for at least two occasions 8 hours apart, is able to take food by mouth, and there are clinical signs of improvement [140]. Initial PCT level may accurately predict positive blood cultures among pneumonia patients and serial measurements help with antibiotic de-escalation and withdrawal in CAP patients [98,141]. In a randomized trial of antibiotic therapy in the ICU, PCT-guidance led to a reduction in duration of therapy compared to standard care for all patients, including those with severe CAP [142]. A recent meta-analysis of 14 randomized trials favored a PCT based treatment algorithm for antibiotic de-escalation without an increase in either mortality or treatment failures [143].

### Treatment of Community-Acquired Methicillin-Resistant *S. Aureus*

Patients with recent influenza should be treated for *S. aureus*, including community-acquired methicillin-resistant *S. aureus* (CA-MRSA), in addition to the other usual severe CAP pathogens. CA-MRSA is different from nosocomial MRSA, as it occurs in previously healthy people, can carry the Panton–Valentine leukocidin gene (a virulence factor which is associated with tissue necrosis), and causes a necrotizing, often bilateral severe pneumonia [70]. The best therapy for CA-MRSA is unclear, but the options include vancomycin, linezolid, or the combination of vancomycin and clindamycin. The latter two regimens have the ability to inhibit
bacterial toxin synthesis (by linezolid or clindamycin), which may be part of the pathogenesis of severe CA-MRSA infection, but current recommendations are not definitive about whether antitoxin therapy is needed [5]. In a recent study of 133 patients with PVL positive CAP, treatment with antibiotics having antitoxin effects (clindamycin, rifampin, and linezolid) was associated with a reduced mortality compared to those who did not get antitoxin therapy (6.1% vs. 52.3%, \( p < 0.001 \)), although only about one-third of patients received this therapy [144].

Role of Steroids for CAP

The role of low-dose (replacement) steroids in septic shock has been the topic of numerous studies, and relative adrenal insufficiency occurs in a high proportion of patients with severe CAP [145]. Salluh et al. [146] have shown that in patients with severe CAP, median cortisol levels were 15.5 \( \mu g \) per dL, and 65% of patients met the criteria for adrenal insufficiency (cortisol levels <20 \( \mu g \) per dL). When patients with septic shock were evaluated, 63% had adrenal insufficiency. A recent meta-analysis of nine trials involving 1,001 patients did not support routine use of corticosteroids for CAP patients, but may improve mortality in a subset with severe CAP [147]. Torres and associates in a randomized, prospective study found that in patients with severe CAP and high levels of inflammation (elevated CRP >15 mg per L) at admission, administration of intravenous methylprednisolone (bolus of 0.5 mg/kg/12 h) led to less treatment failure compared to placebo, but there was no significant difference in hospital mortality between the two groups [148]. In another recent meta-analysis of 13 randomized controlled trials, adjunctive systemic corticosteroid therapy reduced mortality by approximately 3%, need for mechanical ventilation by approximately 5%, and hospital stay by approximately 1 day among patients with CAP and PSI score IV or higher, and CURB-65 score of two or higher [149]. These results suggest that steroid use in the setting of severe CAP does not appear to be harmful, but routine use in severe CAP is not recommended, but may have value for selected patients with high levels of systemic inflammation. Another setting in which corticosteroids may have benefit is in pneumococcal pneumonia that is complicated by meningitis, where pre-treatment with corticosteroids, prior to antibiotic therapy, may lead to more favorable neurologic outcomes [150]. In addition, corticosteroids have benefit in the therapy of \( P. jiroveci \) pneumonia with hypoxemia (\( \text{PaO}_2 < 70 \text{ mm Hg on room air} \)).

Hospital-Acquired Pneumonia, Including VAP and HCAP
To select the optimal therapy for these infections, it is important to have knowledge of patterns of bacterial infection and antibiotic resistance in a given ICU, understanding that the bacteriology varies from one ICU to another. As with CAP, for most patients, initial therapy is empirical, and if that therapy is “inappropriate” (i.e., not active against the etiologic pathogen), then mortality is higher than if the therapy was appropriate [4]. The key decision point in initial empiric therapy is to determine whether the patient has risk factors for MDR pathogens, as outlined in Table 181.2. Early onset of HAP, within the first 4 days of hospitalization, is only one factor to consider when defining whether the patient is at risk for MDR pathogen infection [4]. To be considered not at risk for MDR pathogens, the patient must have both early onset of infection, and no risks for HCAP such as recent hospitalization, treatment in a health care–associated facility (nursing home, dialysis center, among others), and the patient should not have received antibiotic therapy in the past month. However, we may not know all the risk factors for MDR pathogens, and some recent data have shown that even among patients with early-onset infection, and no known MDR risks, up to half of these patients may still have MDR pathogen infection. This may relate to a high frequency of MDR pathogens, even without other risk factors, in patients with severe sepsis and in those treated in an ICU with more than 25% of the pathogens being MDR [151]. On the other hand, patients with either late-onset infection, or the presence of any of the other MDR risk factors, regardless of time of onset of infection, are at risk for infection with MDR Gram-negative and Gram-positive pathogens (Table 181.2). It is essential that initial empirical therapy be appropriate, and that it be given as soon as possible, since changing antimicrobial therapy once culture results are available may not reduce the excess mortality associated with initial inappropriate treatment. The need to get initial therapy correct has led to many patients receiving a broader spectrum regimen than may be needed, and thus it is necessary to obtain cultures prior to therapy, and to use the results to de-escalate to fewer drugs, and narrower spectrum therapy, after 2 to 3 days.

Guidelines make a distinction between appropriate therapy and adequate therapy, with both requiring the use of an agent to which the etiologic pathogen is sensitive. However, adequate therapy also requires that the drug penetrates to the site of infection, and that it is administered in the correct dose and with multiple agents if required. The regimens listed in Table 181.10 are directed at providing appropriate therapy that is targeted to the most likely pathogens. Therapy for those
who are not at risk for MDR pathogen infection can be with a second- or third-generation cephalosporin, a β-lactam/β-lactamase inhibitor combination, ertapenem, a quinolone (moxifloxacin or levofloxacin), or, for penicillin-allergic patients, quinolone monotherapy, or the combination of clindamycin and aztreonam. Therapy for those at risk for MDR pathogens is directed at P. aeruginosa, Acinetobacter spp., ESBL-producing K. pneumonia and Enterobacter spp., and MRSA [4]. Patients at risk for infection with these organisms should initially receive a combination of an antipseudomonal β-lactam plus either an antipseudomonal quinolone (ciprofloxacin or levofloxacin) or an aminoglycoside (amikacin, gentamicin, or tobramycin). The antipseudomonal β-lactams include cefepime, imipenem, meropenem, and piperacillin/tazobactam. Aztreonam can be used for penicillin-allergic patients. This combination regimen is often supplemented with therapy for MRSA with either vancomycin or linezolid.

<sup>a</sup>If an environmental source of Legionella is present, with a known nosocomial outbreak, use fluoroquinolone in the regimen.

To ensure adequate therapy, the right doses have to be used—typically, for critically ill patients with normal renal function, the correct doses of common antibiotics include cefepime 1 to 2 g every 8 to 12 hours; imipenem 500 mg every 6 hours or 1 g every 8 hours; meropenem 1 g every 8 hours; piperacillin–tazobactam 4.5 g every 6 hours; levofloxacin 750 mg daily or ciprofloxacin 400 mg every 8 hours; vancomycin 15 mg per kg every 12 hours leading to a trough level of 15 to 20 mg per L; linezolid 600 mg every 12 hours; and aminoglycosides of 7 mg/kg/d of gentamicin or tobramycin and 20 mg per kg of amikacin [4]. There is interest in optimizing dosing of antibiotics, and this means using continuous or prolonged infusions of β-lactams which are bactericidal in a time-dependent fashion, or giving once-daily high doses of aminoglycosides or quinolones, which are bactericidal in a concentration-dependent fashion. Doripenem has similar efficacy to other antipseudomonal β-lactams for treatment of HAP/VAP and can be given as a 4-hour infusion to ICU patients, with some enhanced efficacy against *P. aeruginosa* when this dosing approach is used, but at least 10 days of
For patients at risk for infection with MDR pathogens, initial empirical therapy should involve a combination of agents, but the role of continued combination therapy is uncertain. One advantage of combination therapy is to provide synergy for the therapy of *P. aeruginosa*, which is accomplished when an aminoglycoside is combined with a β-lactam. Synergy has only been proven to be of value for patients with neutropenia and pseudomonal bacteremia, both uncommon in the therapy of VAP [153]. Although combination therapy could theoretically prevent the emergence of resistance that is common with monotherapy, this has not been proven to be a benefit [154]. The major utility of combination therapy is to provide broader spectrum coverage than is possible with one agent alone, since most hospitals do not have a single agent that is able to cover all the likely pathogens with a high enough frequency. Adding a second agent increases the likelihood that initial empirical therapy will be appropriate, if MDR pathogens are present. In the Canadian Clinical Trials Group study of VAP, the use of combination therapy increased the likelihood of appropriate therapy for patients who had MDR pathogens from 11% to 84%, with an associated improvement in microbiologic eradication [155].

Combination therapy should include agents from different antibiotic classes to avoid antagonism of therapeutic mechanisms. For Gram-negatives, regimens usually involve the combination of a β-lactam with either a quinolone or an aminoglycoside. Although quinolones can permeate into the lung better than aminoglycosides and have less potential for nephrotoxicity, a trend toward improved survival has been seen with aminoglycoside-containing, but not with quinolone-containing, combinations [156]. In some studies, combination therapy has been continued for less than the full course of therapy, with discontinuation of the aminoglycoside after 5 days if the patient is improving [157].

Monotherapy should be used when possible because combination therapy is often expensive and exposes patients to unnecessary antibiotics, thereby increasing the risk of drug toxicity and the selection of antibiotic-resistant organisms. Once cultures are available, if the etiologic pathogen is susceptible, it is possible to change to monotherapy, using one of the agents that has proven to be effective in critically ill ventilated patients with pneumonia due to susceptible pathogens: ciprofloxacin, levofloxacin, imipenem, meropenem, cefepime, and piperacillin/tazobactam [4].

The choice of initial therapy should be based on local patterns of
antimicrobial susceptibility and anticipated side effects, and should also take into account which therapies patients have recently received (within the past 2 weeks), striving not to repeat the same antimicrobial class, if possible. In addition, some studies have shown that recent therapy with quinolones promotes not only Gram-negative resistance to quinolones but also to β-lactams, and they can lead to the emergence of MRSA and MDR Gram-negatives [158]. Therefore, it may be better not to use quinolones for a first episode of hospital infection, because it may make both β-lactams and quinolones less effective when therapy is needed for a subsequent infection [159]. In addition, at many hospitals, Gram-negative susceptibility to quinolones has declined and empiric coverage is improved only if an aminoglycoside is added to a β-lactam, but not if a quinolone is added [160].

For the initial antimicrobial therapy regimen to account for local bacteriologic patterns, each ICU should ideally have its own antibiogram that is updated as often as possible in order to increase the likelihood of appropriate initial antibiotic treatment. Each ICU should establish its own “go to” empiric antibiotic regimen, tailored to the antibiotic susceptibility patterns of the local flora. If patients develop HAP during or shortly after antibiotic treatment for a different infection, the empiric therapy should involve an agent from a different antibiotic class. Recent exposure to a class of antibiotics can predict subsequent resistance to a variety of agents, usually to the same class but occasionally to other classes of agents as well [161].

For the treatment of NP, the guidelines emphasize the need for a “de-escalation” strategy of usage [4]. After 2 to 3 days, the clinical course can be assessed and the culture data reviewed, and in responding patients, efforts can be made to change the initial broad-spectrum therapy. This de-escalation can involve focusing to a more narrow spectrum agent, reducing the number of antibiotics, stopping therapy altogether in patients not likely to have infection, and making efforts to reduce duration of therapy [162]. When this strategy has been used, outcomes such as the frequency of secondary infection, antimicrobial resistance, and mortality have improved. De-escalation can best be accomplished when lower respiratory tract cultures are obtained prior to initiating therapy, although rates can be high with either a nonquantitative endotracheal aspirate or a quantitatively cultured bronchoscopic sample [106]. Negative lower respiratory tract cultures can be used to stop antibiotic therapy for a patient who has had cultures obtained in the absence of an antibiotic change in the past 72 hours and who is clinically doing well. In retrospect, such a patient may not have pneumonia but rather another diagnosis such as CHF or atelectasis. Combination therapy can be de-escalated to monotherapy once culture data are available, and aminoglycosides may be used for a short duration (5 days), when used in
combination with a β-lactam to treat *P. aeruginosa* pneumonia. In clinical practice, physicians do not de-escalate often enough, even though data do not show adverse outcomes when this approach is applied to patients who are responding to initial empirical therapy [163].

The recommended duration of therapy for VAP has been the subject of recent studies. Luna et al. [164] observed that patients who survived VAP after receiving appropriate therapy tended to have clinical improvement by days 3 to 5, especially reflected by improved PaO$_2$/FiO$_2$ ratio, whereas nonresponding patients did not have such a response during the same time period. On the other hand, prolonged antibiotic therapy simply leads to colonization with resistant bacteria, which may be a risk factor for recurrent VAP. A multicenter, randomized, controlled trial demonstrated that patients who received appropriate, initial empiric therapy of VAP for 8 days had outcomes similar to those patients who received therapy for 14 days [165]. A trend to greater rates of relapse for short-duration therapy was seen if the etiologic agent was *P. aeruginosa* or *Acinetobacter* spp. In another study, investigators prospectively randomized VAP patients to receive 15 days (*n* = 109) versus 8 days (*n* = 116) of therapy [166], finding no difference in mortality, ICU length of stay and mechanical ventilation days between both the groups, but more secondary infection in the shorter course cohort than the longer treatment cohort (35.3% vs. 19.3%, *p* = 0.01). Thus, for patients who receive initially appropriate antibiotics and have a good clinical response to therapy, the duration of therapy should be as short as 7 days, provided that the etiologic pathogen is not *P. aeruginosa*. The optimal duration of therapy for VAP due to MDR organisms such as *P. aeruginosa* or *Acinetobacter* spp is not known. Serial measurement of PCT can help guide therapy discontinuation for VAP and help decrease number of days on antibiotic, without having an adverse effect on mortality [86].

Bouadma et al. [142] compared 307 patients with ICU infection who had therapy guided by PCT, compared to 314 controls. The number of antibiotic-free days was approximately 2.7 days less for the PCT group, with no differences in 28- or 60-day mortality between the two groups.

Although aminoglycosides are used in VAP, there is concern about nephrotoxicity (especially among the elderly) and these drugs are less active in areas of the lung that have a low pH level, as may occur with pneumonia. Also, these antibiotics achieve only 40% of the serum concentration in respiratory secretions, when given intravenously. Although once-daily dosing has been proposed to take advantage of the postantibiotic effects of aminoglycosides to enhance efficacy, while
reducing the need for monitoring serum levels and reducing the toxicity, a meta-analysis has shown neither enhanced efficacy nor reduced toxicity with once-daily dosing [4]. Another approach used by some investigators is the direct delivery of aminoglycosides into the airway in an effort to achieve high levels of antibiotic at the site of infection, with little risk of systemic absorption and toxicity [167]. One side effect of aerosolized antibiotics has been bronchospasm, which can be induced by the antibiotic or the associated diluents present in certain preparations. Pending further investigation, this therapy should be used as an adjunct to systemic antibiotics, for patients with severe Gram-negative pneumonias who are not responding to intravenous therapy, or for patients infected by a relatively resistant organism that might be eliminated only with high local drug concentrations.

**HCAP Treatment**

Some patients with health care–associated infections are bacteriologically similar to hospital-acquired infections and also at risk for infection with MDR pathogens [82], but some studies have shown that not all HCAP patients are at the same risk [168]. In the 2005 ATS/IDSA guidelines patients with HCAP were thought to be at risk for infection with MDR pathogens, needing empiric broad-spectrum therapy [4]. However, some studies have shown efficacy for antibiotic regimens for HCAP that are often monotherapy, and similar to CAP therapy [169–172]. Falcone and colleagues found that HCAP patients receiving a guideline concordant regimen had a significantly shorter duration of antibiotic therapy (median 15 vs. 12 days), a shorter duration of hospitalization (median 18 vs. 14 days), and a lower mortality rate (17.8% vs. 7.1%) than those receiving other therapies [170].

Shindo and associates in a prospective study including 1,413 patients (887 CAP and 526 HCAP) determined the risk factors for drug-resistant pathogens (DRPs) to macrolides, β-lactam and respiratory fluoroquinolones (CAP-DRPs) [173]. They found HCAP patients had a higher frequency of CAP-DRPs than patients with CAP (26.6% vs. 8.6%) and higher 30-day mortality (20.3% vs. 7.6%). Independent risk factors for CAP-DRPs in this population included - prior hospitalization, immunosuppression, previous antibiotic use, gastric acid-suppressive agents, tube feeding, and nonambulatory status. In a prospective study, Maruyama and colleagues evaluated 425 patients (CAP = 124, HCAP = 321), and applied a therapeutic algorithm based on the presence of MDR risk factors (immunosuppression, hospitalization within the last 90 days, poor functional status—Barthel Index score <50, and antibiotic therapy within the past 6 months) and severity of illness (need for ICU admission or requiring mechanical ventilation) to determine outcomes [174]. HCAP
patients admitted to the ICU, with at least one MDR risk factor were treated with a HAP regimen based on the ATS/IDSA 2005 guidelines. This represented only two-third of the ICU admitted patients, so that one-third were treated with a narrower spectrum, CAP-type regimen, and the outcomes for all were good. In the entire study group, using the algorithm, 92.9% received appropriate therapy for the identified pathogens. Thus not all HCAP patients need MDR coverage, and some can be effectively treated with a narrower spectrum regimen.

Other Issues

For the therapy of NP, in addition to *P. aeruginosa*, the other challenging Gram-negative organisms are *Acinetobacter* spp. and ESBL-producing *Enterobacteriaceae*. For both groups of pathogens, a carbapenem is the most effective therapy, if the organisms are sensitive, but if not, then novel therapies may be needed. *Acinetobacter* can be treated with tigecycline but generally not as monotherapy, since it has not shown efficacy in clinical trials when utilized this way. In a large double-blind, randomized, multicenter trial comparing imipenem/cilastatin to tigecycline in 945 HAP patients, those patients with VAP who were treated with tigecycline had a significantly lower cure rate and more deaths compared to patients with imipenem [175]. Colistin, a polymyxin, may be necessary in this setting, with some risk of nephrotoxicity. For multidrug-resistant *Acinetobacter* infection, a combination regimen is usually recommended and can include colistin, sulbactam, tigecycline and/or an inhaled antimicrobial [176].

The treatment options for suspected MRSA pneumonia have been expanded with the availability of agents such as the oxazolidinones (linezolid), telavancin, teicoplanin and streptogramins. Linezolid achieves higher lung epithelial lining fluid concentrations compared to glycopeptides and could therefore have an advantage for MRSA lung infections. However, results from two older meta-analyses demonstrated comparable clinical and microbiologic success with using linezolid and glycopeptides and a significant twofold increase in the risk of thrombocytopenia and gastrointestinal events with linezolid [177,178]. In a subset analysis of two prospective, randomized trials, linezolid had a clinical and microbiologic advantage over vancomycin for patients with documented MRSA VAP [179]. This advantage may be due to the higher penetration of linezolid into the epithelial lining fluid than with vancomycin [180]. Since those analyses, a multicenter prospective randomized trial of linezolid versus vancomycin for patients with documented MRSA pneumonia was completed, and linezolid led to a significantly higher rate of clinical response than optimally dosed vancomycin [181]. However, there was no difference in mortality between
the two groups, but this could potentially be explained by the fact that patients, who failed vancomycin, were able to be salvaged with linezolid, and any survival in this setting was attributed to vancomycin. Linezolid may also be preferred if patients have renal insufficiency or are receiving other nephrotoxic agents such as aminoglycosides, because of concerns of synergistic nephrotoxicity with vancomycin, but this is not conclusively proven. Linezolid is generally well tolerated, but patients must be monitored for drug-induced thrombocytopenia, especially after prolonged use (>14 days). Another recent meta-analysis that also included the new randomized controlled trial of linezolid versus vancomycin did find a higher microbiologic eradication rate for linezolid and more nephrotoxicity when glycopeptides (vancomycin or teicoplanin) were used [182]. Quinupristin/dalfopristin is an option but was less efficacious compared with vancomycin in treatment of NP caused by MRSA [183].
STRATEGIES FOR PREVENTION OF PNEUMONIA

Community-Acquired Pneumonia

Preventive strategies can be applied in the outpatient (prehospital) setting or in the hospital and ICU. Outpatient measures proven to reduce the incidence of severe lower respiratory tract infection are immunization against pneumococcal and influenza infection in susceptible populations. The pneumococcal polysaccharide vaccine (PPV) is directed at 23 strains of pneumococcus (accounting for 85% to 90% of all infections), and it is both cost-effective and potentially cost saving among individuals older than 65 years for the prevention of bacteremia. In a study of US hospitals, prior vaccination against pneumococcus was associated with improved survival (adjusted OR, 0.50; 95% confidence interval, 0.43 to 0.59), decreased chance of respiratory failure or other complications, and decreased length of stay among hospitalized patients with CAP [184].

With documented effectiveness of 75% in this age group, the recommendation is that all immune-competent patients aged 65 years or older should be immunized [5]. If prior history of vaccination is not available, revaccination is also safe, as there was no difference in the risk of adverse events following more than three doses of PPV, compared with one or two doses [185]. This may be relevant following vaccination with 23-valent PPV, because pneumococcal antibody levels decline to prevaccination levels within 6 to 10 years. Two protein-conjugated pneumococcal vaccines have been licensed and are more immunogenic than the older vaccine, but contain only 7 and 13 serotypes [5]. The 13-valent pneumococcal conjugate vaccine (PCV13) was approved by the Food and Drug Administration (FDA) in late 2011 for use among adults aged ≥50 years [186]. Based on a randomized, placebo-controlled trial evaluating the efficacy of PCV13 for preventing CAP among adults aged ≥65 years (CAPITA—Community Acquired Pneumonia Immunization Trial in Adults), the Advisory Committee on Immunization Practices recommended routine use of PCV13 among adults aged ≥65 years since Aug 2014 [186]. PCV13 should be administered in series with the 23-valent PPV, giving PCV 13 first, if possible. PCV 13 and PPV 23-valent vaccination are also recommended for patients with chronic pulmonary diseases, receiving steroids or immunomodulating therapy, or who have concurrent sickle cell disease or other hemoglobinopathies, primary immunodeficiency disorders, human immunodeficiency virus infection/acquired immunodeficiency syndrome, nephrotic syndrome,
and hematologic or solid malignancies [187].

Annual influenza vaccination has reduced the frequency and severity of influenza among the elderly and chronically ill patients, and vaccination of medical personnel may reduce nosocomial transmission of influenza from staff to patients. For those above 65 years of age an higher dose influenza vaccine (60 μg of hemagglutinin per strain) has been shown to provide better protection [188,189]. In one study, patients ≥65 years, who had received high-dose inactivated influenza vaccine during the 2012 to 2013 influenza seasons were less likely to have influenza-related medical encounters and hospitalization than standard-dose vaccine [190]. Antiviral chemoprophylaxis (with oseltamivir, zanamivir, amantadine, or rimantadine) may be adjunctive to immunization and is 70% to 90% effective in avoiding infections with influenza A, if it is started at the earliest recognition of an outbreak, and if the circulating strain is sensitive to these agents (which has not always been the case in recent epidemics). The neuraminidase inhibitors, zanamivir and oseltamivir, are active against both influenza A and B, for prophylaxis and if treatment is started within 36 hours of the onset of symptoms [191].

**Nosocomial Pneumonia**

In the ICU, several general strategies may be used to reduce the incidence of pneumonia (Table 181.11). In general, it is possible to reduce the incidence of VAP, but this requires the use of multiple interventions together, which are often administered in the form of a “Ventilator bundle.” The use of these bundles has been effective at reducing the incidence of VAP, particularly if the implementation of the bundle is closely monitored [192]. Typically a bundle includes: hand washing, daily interruption of sedation, daily weaning trial, head of bed elevation, oral care (possibly with chlorhexidine), deep venous thrombosis prophylaxis, and stress ulcer prophylaxis. Bundles have been effective for reducing VAP rates but it is controversial whether it is possible to achieve a “zero VAP” goal [193].

<table>
<thead>
<tr>
<th>TABLE 181.11 Preventive Strategies Available in Intensive Care Unit Pneumonia</th>
</tr>
</thead>
<tbody>
<tr>

</tr>
<tr>
<td>• “Ventilator bundles”: individualize to each ICU</td>
</tr>
</tbody>
</table>
• Oral care, possibly with chlorhexidine
• 24 h of prophylactic systemic antibiotics following emergent intubation
• Change ventilator circuits only when soiled
• Noninvasive ventilation when possible
• Reduce use of nasogastric tubes (place orally, and if possible postpyloric)
• Daily interruption of sedation
• Infection control: hand washing, isolate patients with resistant organisms

To be considered in most patients
• Prophylactic PEEP of 5–8 cm
• Closed suction catheter systems
• Maintain endotracheal tube cuff pressure to avoid aspiration
• Avoid immunosuppressants
• Restricted blood transfusion policy
• Glycemic control
• Influenza and pneumococcal vaccine: consider hospital-based programs

Require further data prior to being adopted for routine use
• Ideal head position: elevated vs. lateral Trendelenburg
• Endotracheal tube biofilm removal or avoidance: silver-coated endotracheal tube, other devices when available
• Subglottic secretion drainage endotracheal tubes
• “Selective digestive decontamination”—oropharynx and GI tract
• Probiotics into the GI tract
• Early tracheostomy
• Silver-coated endotracheal tube
• Polyurethane and conical endotracheal tube cuffs

GI, gastrointestinal; ICU, intensive care unit; PEEP, positive end-expiratory pressure.
Infection Control and Ventilator Equipment Handling

Handwashing, although simple and effective in reducing the spread of resistant organisms, is frequently neglected in the ICU. Proper disinfection of nebulization equipment should be done after each use. Heat moisture exchangers in the ventilator circuit can eliminate the need for cascade humidification but have not been shown to reduce the incidence of NP. Ventilator circuit changes should be made no more often than every 48 hours, and more frequent changes and manipulations may add to the risk of infection [4]. In fact, there is no increased infection risk if tubing is never changed [194]. Micro-aspiration of gastric contents is facilitated by the underinflation of the tracheal cuff pressure and can be effectively prevented by maintaining the tracheal cuff pressure by use of an automated pneumatic device, or by close monitoring of the cuff pressure [195]. In addition, maintenance of PEEP at 5 to 8 cm may also keep the endotracheal tube cuff sealed, and minimize secretion leakage around the cuff. Biofilm formation on the inner surface of the endotracheal tube can be inhibited by using an endotracheal tube coated with silver. In a multicenter trial involving intubated patients, those who had silver-coated endotracheal tubes had lower rates of microbiologically confirmed VAP compared to the control group with uncoated tube (4.8% vs. 7.5%; \( p = 0.03 \)), but there were no differences in the duration of intubation, or mortality among the two groups [55]. There are also a variety of devices under development that can remove the biofilm once it has formed.

Prophylactic Antibiotics

Intense interest has been focused on “SDD” as a means of preventing both NP and sepsis. This approach attempts to sterilize the intestine and oral cavity of all Gram-negative organisms, assuming that the gastrointestinal tract is the source of the organisms that cause pneumonia. Several large meta-analyses and four recent prospective trials have shown a benefit for SDD in preventing VAP and in reducing mortality [196]. The full regimen is usually a combination of topical (polymyxin, tobramycin, and amphotericin or related compounds) and systemic antibiotics (nonpseudomonal third-generation cephalosporin), but the use of only topical oral antibiotics (selective oral decontamination [SOD]) or oral antiseptics (such as chlorhexidine) has also reduced the incidence of infection. In a large randomized trial, both SDD and SOD reduced ICU mortality rates [197]. In spite of these possible benefits,
widespread use of SDD in all ICU patients has not been adopted outside of certain European centers and in many studies, the benefits have applied only to selected populations such as surgical and trauma patients, with less benefit to medical patients. In addition, those at the extremes of disease severity (mild or severely ill) may not benefit, and the incremental benefit of these approaches when added to an effective ventilator bundle, has not been evaluated. To be fully effective, SDD needs to be used in all patients in a given ICU, and this widespread use has been shown in some studies to promote the emergence of resistant bacteria, particularly Gram-positives such as MRSA. This is likely to be an even greater problem for ICUs with a high baseline rate of resistance. SDD may also lead to an increased rate of hospital-acquired infections in patients after they leave the ICU [198]. In a prospective, randomized, double-blind study of 350 patients undergoing cardiac surgery, use of chlorhexidine gluconate 0.12% oral rinse reduced the incidence of pneumonia by 69% in comparison with controls (5/173 vs. 17/180; \(p < 0.05\)). There was no difference in antibiotic resistance patterns in either group [199]. Recently, there is some question about whether oral chlorhexidine can be harmful, possibly related to toxicity if aspirated, and a limited efficacy and higher mortality among noncardiac surgery patients [200]. Another recent meta-analysis of 28 randomized controlled trials supported the use of SOD in the prevention of VAP. In fact, the entire regimen of SDD may not be any more effective than the use of oral antiseptics [201].

The concept of antibiotic rotation or cycling has also been investigated as a resistance control strategy [145,157,182,202], and although there was initial enthusiasm for this approach, recent studies have been less supportive, and most ICUs focus on antimicrobial stewardship, focusing on monitoring local patterns of resistance and introducing heterogeneity into the choice of antibiotics [157,203].

**Control of Respiratory Secretions**

Stagnation of respiratory secretions can lead to both pneumonia and atelectasis, and efforts to remove these secretions could reduce the incidence of pneumonia. One way to achieve this objective is through the use of continuous lateral rotation delivered by a rotating bed that is used in place of a traditional hospital bed to improve mucociliary clearance and help mobilize secretions. Another way to control respiratory secretions is to remove oropharyngeal contents before they can be aspirated into the lung. Continuous aspiration of subglottic secretions, through the use of a specially designed endotracheal tube, has significantly reduced the incidence of early-onset VAP in several studies [4]. Subglottic drainage aspiration (SSD) can be achieved by a specially
adapted endotracheal tube that will allow suctioning of secretions that pool above the endotracheal tube cuff, thereby interrupting the aspiration of secretions into the tracheobronchial tree. A recent randomized control trial showed a significant reduction of microbiologically confirmed VAP with the use of SSD, compared to the control population (14.8% vs. 25.6%; \( p = 0.02 \)) but no difference in duration of mechanical ventilation or mortality [204]. In another randomized study enrolling over 700 patients comparing continuous aspiration of subglottic secretions (CASS) versus controls after cardiac surgery, the CASS group had lower VAP rate (26.7% vs. 47.5%; \( p = 0.04 \)), and fewer days in the ICU (7 vs. 16.5 days; \( p = 0.01 \)) [205].

**Stress Ulcer Prophylaxis**

Several clinical studies have documented that neutralization of gastric pH with antacids or H₂ blockers can add to the risk of NP (especially late-onset infection) among mechanically ventilated patients [4]. Although not all studies have shown that the gastric reservoir is an important source of infection, prevention strategies should take into account its potential influence by minimizing gastric volume and preventing aspiration of gastric contents; however, ventilator bundles have been able to reduce VAP rates, even when H₂ blockers are used. This is likely because gastric acid neutralization is combined with elevation of the head of the bed, which may prevent aspiration of gastric contents. Although some studies have suggested a benefit of performing stress ulcer prophylaxis with sucralfate, at least one large, double-blind, randomized trial comparing ranitidine with sucralfate, demonstrated a trend toward lower rates of VAP with sucralfate, but reported that clinically significant gastrointestinal bleeding was 4% higher in the sucralfate group [206].

**Ventilator Bundles**

The incidence of VAP can be reduced substantially if there is a high rate of compliance with all the interventions in a ventilator bundle. Bundle use has been reported to lead to almost 45% reduction in the incidence of VAP and the benefit was greatest when adherence to the protocol was high [192]. In the last several years, this approach has become so popular and apparently effective that many believe that it can lead to a “zero VAP” rate. However, there is concern that the benefits of ventilator bundles have been overstated, and that it is impossible to eliminate VAP in certain high-risk patients [207]. Thus, it is unclear if VAP is really being prevented, or if the disease is being diagnosed less often, especially given the subjective nature of the VAP definition, and the possibility of treating patients for another diagnosis. In addition, although studies have shown
a reduction of VAP rates, secondary benefits such as reduction in mortality and antibiotic use have not generally been reported.

Advances for managing acute infectious pneumonia, based on randomized, controlled trials or meta-analyses of such trials, are summarized in Table 181.12.

**TABLE 181.12  Recent Advances in Pneumonia Management Based on Randomized Trials, Large Database Analyses, and Meta-analysis**

- Antibiotic duration in VAP should be as short as possible. In patients with a low clinical suspicion, based on serial clinical observations and improvement, therapy can be stopped after 3 d, while those with microbiologically confirmed VAP can be safely treated for 8 d, provided that initial therapy is appropriate and that a nonfermenting Gram-negative is not responsible [61,150].

- Linezolid is associated with a lower mortality and higher bacteriologic eradication rate than vancomycin in patients with VAP that is proven to be caused by MRSA, but quinupristin/dalfopristin is not superior to vancomycin [122,137,139].

- Quinolone monotherapy should not be used for patients with severe CAP, since it has not been proven to be safe and effective for all of the types of patients admitted to the ICU [4,118].

- Patients with severe CAP should receive combination therapy, generally with a beta-lactam and a macrolide. Meta-analysis has shown reduced mortality for severe CAP patients treated with a macrolide [129].
• Mortality in CAP can be reduced by administering the first dose of antibiotics as soon as possible after a patient’s arrival to the hospital [4].

• In patients with VAP, an etiologic diagnosis can be made with either endotracheal aspirate culture or bronchoscopic culture, with no difference in mortality, comparing the 2 methods [2].

• Combination antimicrobial therapy in VAP increases the likelihood of initially effective empiric therapy for patients who are likely to have multidrug-resistant pathogen infection, but the use of combination therapy has not been definitively proven to reduce mortality [2].

• When cephalosporins are used for empiric therapy of severe CAP, and drug-resistant S. pneumoniae is suspected, ceftriaxone and cefotaxime are reliable choices, while cefuroxime is not [4].

• In the presence of CAP with pneumococcal bacteremia, use of dual antibiotic therapy is associated with reduced mortality, compared with monotherapy, especially for patients with severe pneumonia [115,116].

Interventional pulmonology (IP) is a relatively new field in pulmonary and critical care medicine that involves the use of advanced procedures for the diagnosis and treatment of tracheobronchial and pleural disorders. Since the introduction of endobronchial laser therapy and the “dedicated tracheobronchial silicone stent” by Dumon in 1990 [1] mainly in response to the rising prevalence of lung cancer in the 1980s [2], the specialty has evolved to target a wide spectrum of benign and malignant respiratory pathologies.

The treatment of complex airway diseases needs specialized training that is beyond the scope of a general pulmonary and critical care fellowship [3]. Guidelines that attempt to ensure basic skill and competency for all procedures encompassed within the specialty have been published by major societies, including the American College of Chest Physicians (ACCP), the American Thoracic Society (ATS), and the European Respiratory Society (ERS) [3,4]. Starting in 2013, the American Association of Bronchology and Interventional Pulmonology (AABIP) has started board examinations and certification to ensure competency within the field (Table 182.1). Interventional Pulmonary Fellowships now participate in the National Residency Matching Program (NRMP).

| TABLE 182.1 Current Requirements for Interventional Pulmonary Board Certification by the AABIP |
|-----------------------------------------------|-----------------------------------------------|
| Core procedural groups                        | Minimum number of procedures (3 years total)  |
| Complex Airway Diseases                       | 90                                            |
| Rigid or Flexible Bronchoscopy                |                                               |
Airway interventions—benign and malignant
Any combination of mechanical debulking, laser, APC, electrocautery, cryotherapy, stents (hybrid/silicone), or other endoscopic modality, brachytherapy, PDT, or emerging technologies
Other flexible or rigid interventions not easily classified elsewhere: endobronchial valves, blockers, bronchial thermoplasty, etc.

Advanced Diagnostic Bronchoscopy
90
Peripheral lung lesions and mediastinal assessment
Any combination of navigation; radial probe EBUS or virtual bronchoscopy guided transbronchial sampling; Convex Probe EBUS; and other emerging technologies

Pleural disease management
90
(Medical thoracoscopy/pleuroscopy optional)
Any combination of minimally invasive diagnostic and therapeutic procedures including thoracic ultrasound-guided thoracentesis, tube thoracostomy, indwelling pleural catheter, closed pleural biopsies, and thoracoscopy.

Percutaneous tracheostomy and percutaneous endoscopic gastrostomy
Optional for IP fellowship training and board eligibility

Multidisciplinary patient management conferences or other didactic conferences
Yes
Any combination of tumor board, multidisciplinary clinics, transplant selection committee meetings, etc.

AABIP, American Association for Bronchology and Interventional Pulmonology; APC, argon-plasma coagulation; PDT, percutaneous dilatational tracheostomy; EBUS, Endobronchial ultrasound; IP, interventional pulmonology.

As a main feature, the uses of the rigid bronchoscope, and its many applications for treatment and palliation, require expertise not only in the procedures themselves, but, as importantly, in selecting those patients who might benefit from an intervention. Given the nature of the disease processes the field encounters, an important proportion of patients will have significant comorbidities and limited functional status that need to be considered prior to any procedure.

There are multiple applications for the field of IP in the intensive care unit (ICU). Because, the subspecialty frequently serves patients requiring ICU level of care, the interventional pulmonologist is a valuable member of the ICU team. In the current chapter, we address some of the
techniques at the disposal of the interventional pulmonologist and how these may be applied to the ICU setting (Table 182.2); it is not the intention of this chapter to describe in detail the entire range of procedures performed by the subspecialty of IP.

| TABLE 182.2 Procedures that May Be Performed by Interventional Pulmonologists in the ICU |
|-------------------------------------------------|--------------------------------|---------------------------------|
| Airway procedures                              | Pleural procedures            | Other procedures                |
| Flexible and rigid bronchoscopy                | • Chest ultrasonography       | • Percutaneous endoscopic gastrostomy |
| Diagnostic:                                    | • Thoracentesis               |                                 |
| Transbronchial lung biopsy                     | • Tube thoracostomy           |                                 |
| Transbronchial needle aspiration               | • Placement of pleural catheters |                                 |
| Endobronchial ultrasound                       | • Transthoracic needle aspiration/biopsy |                                 |
| Therapeutic:                                   |                                 |                                 |
| Airway stent placement                         |                                 |                                 |
| APC                                             |                                 |                                 |
| Nd:YAG Laser                                   |                                 |                                 |
| Electrocautery                                  |                                 |                                 |
| Cryotherapy                                     |                                 |                                 |
| Balloon dilatation                              |                                 |                                 |
| Endobronchial valves                            |                                 |                                 |

AIRWAY PROCEDURES

Rigid Bronchoscopy

The first successful removal of an aspirated foreign body by a translaryngeal approach was done with a rigid bronchoscope by Gustav Killian in 1897 [5]. Until that time, foreign body aspiration could be severely incapacitating and resulted in chronic illness from recurrent infections, atelectasis, hemorrhage, or death [5]. The rigid bronchoscope was later used for other diagnostic and therapeutic procedures. Since the invention of the flexible bronchoscope by Shigeto Ikeda in 1968 [6], the
The rigid bronchoscope is a stiff metallic tube that is introduced by a trans-laryngeal approach and allows for ventilation and passage of different instruments. There is a longer bronchial barrel with side fenestrations to allow for collateral ventilation while intubating the right or left bronchus, and a shorter tracheal barrel that has no side fenestrations and is used for intubation of the trachea. At its proximal end, the rigid bronchoscope provides the connections for mechanical ventilation and passage of the light source. The distal end has a beveled tip that can be used for coring out endoluminal lesions. The airway lumen may be projected to a screen using a telescope with a camera attachment or may be visualized directly through an eye piece (Fig. 182.1).

Massive Hemoptysis

The anatomical dead space of the central airways is approximately 100 to 200 mL; a rapid bleed close to this volume may be enough to cause central airway obstruction (CAO), asphyxiation, and death. The exact quantity of blood that defines massive hemoptysis has been estimated to be from >200 to 1,000 mL in a 24-hour-period, but it seems more practical to keep in mind that any bleed that could be life-threatening
should be considered massive [8]. Causes of massive hemoptysis include malignancies; tuberculosis; fistulas from major vessels; and bronchiectasis.

When confronted with massive hemoptysis, one should start by ensuring stability of the patient by providing appropriate means for oxygenation and ventilation. It is important to keep in mind that the patient with hemoptysis may already have a very limited functional status and that respiratory failure may happen very rapidly. For the unstable patient, endotracheal intubation should not be delayed and—in addition to general measures that include placing the patient with the bleeding side down, establishing appropriate intravenous access, and sending appropriate laboratory testing—no time should be wasted in identifying and controlling the source of bleeding. Oftentimes, the source of bleeding may be identified by radiologic studies and controlled by angiographic embolization, but in cases when chest imaging is unrevealing or the bleeding source is thought to be within the airways, one should proceed with diagnostic and therapeutic bronchoscopy [9].

Massive hemoptysis has a high mortality rate, and it is paramount to secure airway patency, identify the bleeding source and apply therapeutic interventions to stop the bleeding. The rigid bronchoscope is superior to the flexible bronchoscope for all these functions because it allows for ventilation and more vigorous suctioning that may help secure the airway and visualize more thoroughly the source of bleeding. Also, if the cause of hemorrhage is endobronchial, rigid bronchoscopy provides a way to control the bleeding with cauterizing modalities such as electrocautery, argon plasma coagulation (APC), or laser therapy. The use of other hemostatic therapies such as iced saline, epinephrine, fibrin glue, oxidized regenerated cellulose, or the placement of occlusive balloons, may all be applied successfully through the rigid barrel while maintaining airway patency [8–13]. For these reasons, the rigid bronchoscope remains the instrument of choice for the endoscopic assessment and treatment of massive hemoptysis.

Central Airway Obstruction

CAO is a problem that may be encountered in the ICU. It may be because of either benign or malignant etiologies. Patients often experience progressive dyspnea on exertion when the narrowing involves 50% of the airway lumen, then developing dyspnea at rest when the stenosis reaches 70% of the airway lumen [14]. When the stenosis is severe, a seemingly stable patient may rapidly develop an acute, critical occlusion of the central airway because, for one example, an otherwise mild respiratory tract infection has caused an increase of secretions that are poorly cleared by ineffective cough, occluding the already severely narrowed airway at or
near the site of the stenosis.

Nonmalignant Central Airway Obstruction

Nonmalignant CAO may result from inflammatory conditions such as sarcoidosis, amyloidosis, antineutrophil cytoplasmic autoantibodies (ANCA)-associated vasculitis, or relapsing polychondritis. Benign disease processes also may occlude the central airway by extrinsic compression and this may be seen in large goiters, post-pneumonectomy and post-lung transplantation stenosis and vascular malformations. Finally, tracheobronchomalacia also may result in CAO because the abnormally collapsible airway can occlude the central airway lumen during expiration. However, the most common cause of nonmalignant CAO is stenosis caused by artificial airways, either postintubation or posttracheostomy tracheal stenosis (Table 182.3) [15,16].

</table>
Postintubation and Posttracheostomy Tracheal Stenosis. This is the most common cause of benign tracheal stenosis and results from granulation and fibrotic responses to artificial airways at anatomic loci from the supraglottic space to the lower trachea. The endotracheal tube may cause pressure ulceration and necrosis at any point where the tube contacts the airway wall; this may be the posterior commissure of the glottic space, the balloon site or at the tip of the tube. The same applies for a tracheostomy tube where pressure ulcerations and granulation tissues may form immediately above the stoma within the trachea, at the balloon site or at the tip of a tube that rubs against the airway mucosa. Inflammation, ulceration, and necrosis may in turn result in constriction of the airway wall caused by a loss of support from damaged cartilage, obstruction from granulation tissue, fibrosis, and formation of synechiae. Damage from the balloon has been reduced by the development of high-volume, low-pressure cuffs; however, it remains important not to exceed the normal mucosal capillary perfusion pressure of 20 to 30 mm Hg or tracheal injury may occur because of tissue ischemia. If after achieving a cuff pressure of 25 mm Hg there is still an air leak present, it is advisable to use a larger tracheostomy tube rather than to overinflate the balloon [17].

Tracheal stenosis may become apparent soon after what should have been a successful wean from mechanical ventilation when the patient fails extubation because of stridor and respiratory distress requiring immediate reintubation. However, severe airway narrowing also may present as an airway emergency weeks or months after extubation or tracheostomy decannulation. Not uncommonly, these late deteriorations are preceded by ongoing complaints of worsening stridor or dyspnea on exertion that progress to dyspnea at rest. Frequently, these patients may have been misdiagnosed as having asthma or COPD and gone through treatment with different bronchodilators and systemic steroids without improvement before recognition.

It is important to understand that airway patency is the priority for patients with tracheal stenosis. When the presentation is one of acute
respiratory failure, the patient must be intubated with an endotracheal tube immediately. If an endotracheal tube cannot be advanced, then the patient must be taken to rigid bronchoscopy immediately. More importantly, when confronted with tracheal stenosis the specialist must keep in mind that there needs to be a multidisciplinary approach. Ideally, the intensivist; emergency department physician; thoracic surgeon or otorhinolaryngologist; anesthesiologist; and the interventional pulmonologist collaborate to develop a coherent plan of action that considers different alternatives for a safe and successful approach. When the patient is symptomatic but stable, there may be sufficient time to plan for a procedure that will both assess the stenotic segment and potentially relieve the obstruction. However, if the patient is unstable with acute respiratory failure, restoration of airway patency must occur immediately. If it is not possible to pass an endotracheal tube and the stenosis is felt to be proximal, emergent bedside tracheotomy may become the best option because there may not be enough time to transport the patient to the operating room. However, the latter presentation is unusual when patients first arrive at the emergency department and, often, subsequent deterioration may be averted by carefully planning and by quickly treating the stenosis before overt decompensation occurs.

The rigid bronchoscope is an invaluable tool because it provides the means to successfully maintain the patency of the airway while the patient is being treated endoscopically, either definitively when the stenosis is simple, or temporarily as a bridge to a planned tracheal resection and reconstruction when the stenosis is complex \[16–19\]. The interventionalist has multiple, different therapeutic modalities that may be applied through the rigid bronchoscope to restore airway patency. One method is to use sequentially larger diameter rigid barrels to dilate the airway in a secure and gentle manner. For this method, the patient is intubated with a larger diameter tracheal barrel immediately proximal to the stenosed area and then a smaller diameter bronchial barrel is advanced through the stenosis, allowing for the subsequent advancement of larger caliber bronchial barrels until enough of the lumen is restored for spontaneous breathing. Alternatively, after intubation with a tracheal barrel immediately proximal to the stenotic area, Jackson–Pratt dilators can be advanced sequentially under direct visualization with the rigid telescope. Balloon dilatation may also be done, keeping in mind that the airway is completely occluded while the balloon is inflated. With a very tight stenosis one must use gentle maneuvers because dilating against a fixed stenosis can result in tracheal tears, especially where the anterior wall meets the posterior membrane of the trachea. Such tracheal tears can result in more scarring and further restenosis, possibly involving an even longer segment of the trachea.
Simple airway stenosis typically involves short (<1 cm long) segments of the airway without malacia or loss of cartilaginous support and may have thin web scarring or acute granulation tissue [18,19]. This type of stenosis may be treated definitively with endoscopic treatment [18,19]. The interventional pulmonologist has different therapeutic modalities at his or her disposal and these include coagulation modalities (i.e., electrocautery, laser therapy, and APC) that relieve obstructions by coagulation necrosis and vaporization of scar tissue. A commonly referenced technique involves the use of neodymium-doped yttrium aluminum garnet (Nd:YAG) laser vaporization of scar tissue followed by gentle dilatation [15].

Complex airway stenoses show more extensive scarring (>1 cm long), sometimes featuring a circumferential hourglass-like constriction or malacia. Complex stenoses may also be “A” shaped because of bilateral collapse of the walls of a fractured cartilage (Figs. 182.2 and 182.3) [16]. For complex airway stenoses, tracheal resection and reconstruction is the standard of care and, in experienced hands, this is a highly effective surgical procedure with low morbidity and mortality [17]. For the patient with poor reserve, a temporizing endoscopic procedure, as already described, may be attempted and this is often followed with airway stenting. When airway stenting is done, one approach is to leave the stent in place until the patient is able to undergo definitive surgery or, alternatively, to remove the stent after approximately 6 months to 1 year to assess for resolution of the stenosis, an outcome that is possible but uncommon [19].
FIGURE 182.2 A: A-shaped stenosis with fractured cartilage. B: Complex stenosis with chronic granulation above stoma site. C: Simple stenosis caused by a thin web in ANCA-associated vasculitis, easily broken with the flexible bronchoscope; ANCA, antineutrophil cytoplasmic autoantibodies.
FIGURE 182.3 Complex post-tracheostomy tracheal stenosis with malacia. A: Very narrow trachea lumen with passive expiration. B: Notice dilatation of
the tracheal lumen under positive pressure ventilation.

**Malignant Central Airway Obstruction**

Lung cancer is the leading cause of death from cancer in the USA. It is responsible for one-third of deaths from cancer of both men and women. It outnumbers prostate, breast, and colon cancers combined [2]. There may be airway complications associated with lung cancer up to 30% of the time. When there is airway involvement, patients often present to the ICU with lobar or complete lung collapse, sepsis from post-obstructive pneumonia, or severe dyspnea [20]. It is well established that the relief of malignant CAO may lead to symptomatic and quality of life improvements, reduce work of breathing, and decreased health care utilization [21–23]. Moreover, survival appears to be the same after successful endoscopic treatment of malignant CAO when compared to cancer patients without CAO [24,25].

Malignant CAO may be caused by endobronchial tumor growth, extrinsic compression, or mixed causes (Table 182.3). The rigid bronchoscope may be used for immediate relief of malignant CAO by gently advancing the instrument and, while carefully remaining parallel to the airway wall, rotating the beveled tip around the base of a polypoid lesion to core it out and restore patency of the airway lumen [26]. The rigid bronchoscope also ensures a means to ventilate the patient during the procedure. The flexible videobronchoscope can be advanced through the lumen of the rigid barrel to reach into segmental airways not approachable by rigid bronchoscopy. This technique increases the maneuverability that is needed to apply therapies (e.g., laser, electrocautery, or APC) aiming to eradicate tumor and achieve hemostasis [27].

Since the introduction of the tracheobronchial silicone stent by Dumon in 1990, stents have become an integral part of the relief of both benign and malignant CAO (mostly silicone for the former, and both metallic and silicone for the latter) and are a main feature of the interventional pulmonologists’ skill set [28]. In some instances, airway stents can be a valuable tool for maintaining airway patency once it has been restored. With both benign and malignant disease causing extrinsic compression and sometimes with intrinsic and mixed obstruction as well, it may be necessary to leave an airway stent in place to ensure the stability and patency of the airway lumen (Figs. 182.4 and 182.5). There are two main types of stent, silicone and metallic, and it is generally accepted that, except for very carefully selected situations, metallic stents should be used primarily for malignant disease-related CAO [28]. The rigid bronchoscope provides the only means for deployment of a silicone stent and, it is arguably the best means for the deployment of any type of stent.
because it ensures control of the airway throughout the entire procedure (Fig. 182.6). It is up to the interventionalist to decide when a stent may benefit a patient; what type and size to place; how to care for it; and how to follow up the patient after insertion.
FIGURE 182.4 A: Malignant extrinsic compression left mainstem bronchus. B: Relief of obstruction after stent placement.
FIGURE 18.5 A: Malignant intrinsic obstruction right middle lobe. B: Post-debridement with argon plasma coagulation. C: Stent placed because of residual tumor obstruction in bronchus intermedius.
Recent data from the American College of Chest Physicians Quality Improvement Registry, Evaluation, and Education (AQuIRE) program have shown the benefits of therapeutic bronchoscopy for malignant CAO. The data from fifteen centers performing 1,115 procedures showed successful restoration of airway patency in 93% of all cases. Endobronchial obstruction and stent placement were associated with success, whereas failure was more likely in patients with American Society of Anesthesiology (ASA) score >3, renal failure, primary lung cancer, left mainstem disease, and tracheoesophageal fistula. Symptomatic improvement as assessed by Borg score for dyspnea occurred in 48% of patients, and it seemed to be more significant among patients with greater baseline dyspnea. Health-related quality of life
(HRQOL) as measured by the SF-6D was improved for 42% of patients, and again greater improvements were found in patients with greater baseline dyspnea. The overall complication rate was 3.9%, but there was a significant variation among centers (0.9% to 11.7%; \( p = 0.002 \)) and ASA score \( >3 \), redo therapeutic bronchoscopy, and moderate sedation were all found to be risk factors for complications. The 30-day mortality rate was 14.8%, and this again varied among different centers (7.7% to 20.2%; \( p = 0.02 \)). The findings of the ACQuIRE program reinforce the concept that malignant airway obstruction can often be treated to achieve significant palliation of symptoms and improved quality of life [20].

**Airway Obstruction Caused by Aspiration of Foreign Bodies**

A more common occurrence among children, non-asphyxiating foreign body aspiration may also be seen in adults. Failure to have an effective swallowing mechanism or lack of a strong cough may be a problem encountered by patients with certain predisposing conditions such as alcohol intoxication, narcotic abuse, neuromuscular diseases, and advanced dementia.

The rigid bronchoscope, initially conceived for the removal of aspirated foreign bodies, has lost its central role for this application since the advent of the flexible bronchoscope. There are many accessories that may be employed with a flexible bronchoscope for retrieval of foreign bodies. Some of these include forceps, balloons, baskets, and cryotherapy, the latter being particularly useful for soft, water-rich material. However, for certain instances, it may be more advisable to use the rigid bronchoscope, instead. Through the rigid bronchoscope, one can ensure ventilation even during sometimes laborious and lengthy procedures, especially, for example, when larger instruments are required or when there is granulation tissue covering the foreign body.

**Bronchopleural Fistula**

A bronchopleural fistula (BPF) is a communication between the airway and the pleural space. BPFs occur 1.5% to 28.5% of the time after lung resection with the highest incidence following right pneumonectomy and right lower lobectomy. An air leak through the chest tube postoperatively indicates a communication between lung parenchyma and the pleural space, and these leaks are considered prolonged air leaks (PAL) when
they persist more than 7 days. These PAL are commonly seen after lung resection and seem to be particularly frequent and of longer duration among patients with underlying emphysema or bullous disease. In a review of the National Emphysema Trial (NETT), 90% of patients developed some form of an air leak. Patients with BPF and air leaks have significantly higher morbidity and mortality rate [27,28].

The patient with a BPF may present acutely with severe dyspnea, respiratory distress, or hypotension due to tension pneumothorax. Alternatively, the presentation may be subacute or chronic, when an infected pleural space causes fatigue, wasting, fever, and cough, sometimes with expectoration of purulent material and sepsis. The chest radiograph will reveal an air fluid level. Because the pleural space becomes infected with airway secretions, a drainage procedure is always warranted. The ultimate treatment of a BPF is surgical and usually involves placing a muscle flap over the affected airway. Other risk factors for the development of an air leak include the acute respiratory distress syndrome (ARDS), chest trauma, necrotizing infection, and pulmonary fibrosis [29].

The management of a BPF or an air leak involves general and specific measures [29]. At all times, the pressure gradient between the airway and the pleural space should be minimized, positive pressure ventilation should be avoided when feasible and chest tubes should have the minimal amount of suction required to maintain gas exchange, the goal should not always be to achieve complete lung reexpansion but rather to maintain ventilation and oxygenation [30]. For more detailed management of the patient on the ventilator, please refer to the section on the topic of BPF of Chapter 176 on Pleural Diseases.

For endoscopic management of BPF, there are several options when the defect is small and either parenchymal or an airway defect less than 3 mm in diameter. Endoscopic treatment is very unlikely to work when the airway defect is >8 mm [31,32]. First, if the defect is not immediately visible by bronchoscopy, one option is to advance a Fogarty balloon and selectively occlude different lung segments, starting proximally, until the leak is observed to decrease or disappear. When the site of the leak is localized, several sealants may be applied, such as fibrinogen–fibrin compound; tetracycline and blood clot; ethanol; cyanoacrylate glue; gel foam; coils; silver nitrate; amplatzer occlusion devices; spigots; or stents [30–33] (Fig. 182.7). In a study involving 60 patients with an air leak, spigots were placed with reduction in the air leak in 38% and resolution in 40% [34]. In 2008, the FDA approved Spiration IBV
endobronchial valves for the treatment of PAL after lung resection. These one-way valves are placed bronchoscopically into the affected lung segments. Typically, several valves may be needed to effectively stop or reduce the leak [35].
The standard treatment of a BPF should be surgical if at all possible. When the patient is too frail to undergo a major surgical procedure, endoscopic options may be contemplated. However, the approach to these often challenging cases should be multidisciplinary, involving the intensivist, the thoracic surgeon, and the interventional pulmonologist [36].

**Percutaneous Dilatational Tracheostomy**

Since its description by Ciaglia in 1985, percutaneous dilatational tracheostomy (PDT) has become a very commonly performed procedure in the ICU [37]. Indications are typically the same as those for surgical tracheostomy (ST), including a requirement for long-term ventilatory support; inability to clear secretions; and airway obstruction.

There are several potential advantages of PDT over ST. In a meta-analysis including 17 randomized clinical trials and 1,212 patients, there was a lower risk of infection among patients of the PDT group, possibly related to less manipulation and trauma of pre-tracheal tissues during PDT. There also was a decreased incidence of bleeding and death when patients with PDT were compared to those who had undergone ST performed in the operating room [38]. Another meta-analysis of critically ill patients also compared PDT to ST, and this study showed that although technical difficulties were more common, PDT was associated
with less procedural time and less stoma inflammation [39].

Percutaneous tracheostomy has become a part of the skills set of many intensivists. However, given the steep learning curve and the need for a minimal volume to maintain competency, it seems reasonable to have a few designated physicians performing this procedure at a given institution. The interventional pulmonologists are well suited to be the designated specialists for this technique given their familiarity with airway interventions, especially when considering that short and long-term complications such as bleeding at the stoma site and posttracheostomy tracheal stenosis are often treated by the subspecialty. When performed by an IP team, PDT is safe and has a complication rate that is similar to that of ST performed by a surgical team [40].

Complications of PDT mimic those of ST, and may be short and long term. The short-term complications most often encountered include bleeding and infection; other more rare ones include posterior tracheal injury, subcutaneous emphysema, pneumomediastinum, and pneumothorax. Bleeding is usually venous and non-life threatening, being external or from the endotracheal mucosa at the level of the stoma. Locally, a mixture of lidocaine and epinephrine can be injected to control bleeding. We also have successfully used oxidized regenerated cellulose strips (Surgicel) applied within the bleeding area in the stoma. Movement of the tracheostomy tube or forceful coughing may also cause bleeding within the endotracheal mucosa at the level of the stoma and this may present as frank blood being suctioned by the bedside nurse or respiratory therapist. For this type of bleeding, the interventional pulmonologist can use electrocoagulation techniques such as electrocautery or APC to control severe hemorrhage. A trachea–innominate artery fistula may present as a massive bleeding a few weeks after tracheostomy placement and should be prevented by placing the tracheostomy between the first and second or second and third tracheal rings. Tracheal stenosis and trachea–esophageal fistula may also present as long-term complications and may be occurring more commonly as the number of ICU survivors increases. It remains to be determined whether PDT or ST is superior for avoiding these serious complications.

To minimize the potential complications of PDT, some authorities have proposed the use of bedside ultrasonography to detect large vessels that may pose a significant bleeding risk, as well as for the identification of anatomical landmarks when they are difficult to visualize or palpate, such as in morbidly obese patients [41,42]. Videobronchoscopy also is widely employed to ensure proper placement of the initial needle in the space
between either the first and second or second and third tracheal rings. Again, both techniques are within the typical skills set of the interventional pulmonologist.

Percutaneous Gastrostomy Tube Placement

Since its first inception by Gauderer and colleagues in 1980 [43], the placement of percutaneous gastrostomy (PEG) tubes has gained widespread acceptance for long-term enteral nutrition of patients unable to swallow effectively. The procedure is now routinely performed by surgeons, gastroenterologists, or interventional radiologists. Given their advanced endoscopic and procedural training, interventional pulmonologists may also safely perform placement of PEG tubes in the ICU setting at the patient bedside. When indicated, the PDT and PEG tubes can often both be placed together, at a single procedural session [44].

PEG is usually performed by inserting an endoscope into the stomach and then transilluminating the puncture site through the gastric and abdominal walls. Finger indentation can be seen within the insufflated gastric lumen at the site of transillumination. A skin incision then is made under local anesthetic and an angiocath is advanced through the abdominal wall and into the stomach. A loop is inserted through the angiocath and then grabbed and brought out through the mouth attaching it to the gastrostomy tube. The loop is then attached to the gastrostomy tube such that the tube can be pulled down the esophagus, into the stomach, and through the gastric and abdominal walls for securement at the skin surface. An alternate method uses a pull-away sheath and introduces the tube through the abdominal wall.

The safety and efficacy of PEG placement by an IP team has been demonstrated. In one review of 72 patients undergoing the procedure, PEG tube insertion was successful in 97.2%, with no major complications [44].

Ultrasound Guided Thoracentesis and Placement of Pleural Catheters

Pleural effusions may be seen in up to 62% of ICU patients. Although these are often small effusions not contributing to the patient’s condition, many times they may need to be sampled or drained for diagnostic or therapeutic reasons [45]. The characterization of a pleural effusion as a transudate or exudate, either uncomplicated or complicated, may be very helpful in the management of the ICU patient.

Over the last decade, the use of ultrasonography in the ICU setting has become widespread. Bedside ultrasound allows for the characterization of
the lung and pleural space in a quick, safe and noninvasive way that spares the patient the radiation of chest radiography or computed tomography (CT) [46].

For the assessment and drainage of pleural fluid in patients with or without mechanical ventilation, chest ultrasonography is more sensitive and specific than chest radiographs and is more reliable than physical examination for selecting an appropriate puncture site [47,48]. Chest ultrasonography is also helpful for characterizing pleural effusions because transudates are usually anechoic. Exudates may sometimes be anechoic, but when the fluid is complex (septated, loculated, etc.) or hypoechoic an exudate is more likely [49].

Interventional pulmonologists are thoroughly trained in thoracentesis and placement of pleural catheters under ultrasound guidance, a procedure that may often be indicated for ICU patients with empyema or other effusions requiring complete drainage. The interventionalist considers the entire medical picture to decide whether a thoracentesis or a pleural catheter is best indicated. Pleural catheters also facilitate instillation of fibrinolytics for complicated effusions and chemical pleurodesis for malignant effusions. Additionally, pleural catheters and chest tubes may also be placed by an IP specialist for evacuation of a pneumothorax.

Workup of Solid Lung and Pleural Lesions

Chest ultrasound also may be useful for safely sampling solid lung or pleural lesions. With a large enough acoustic window, a 22G to 25G needle may be advanced, under local anesthetic, into the lesion to aspirate material for cytologic analysis. In addition, a core needle biopsy may be performed. These biopsy samples may be obtained safely by marking the entry site and then using ultrasound to define the safe range, direction and depth of the puncture. Sonographic evaluation for a potential pneumothorax may be done immediately after the aspiration with relative ease. The IP specialist, thoroughly trained in chest ultrasonography and pleural procedures, is often able to safely and effectively obtain valuable histopathologic sampling using these techniques for carefully selected cases.

Related Considerations

Although not exclusive to the realm of interventional pulmonologists, we briefly discuss the role of lung biopsy in the management of critically ill patients with respiratory failure and parenchymal infiltrates. The available approaches include not only surgical lung biopsy but also the use of nonsurgical, bronchoscopic diagnostic modalities such as transbronchial lung biopsies (TBBx), and the burgeoning utilization of
transbronchial cryobiopsies, a newer biopsy technique that may obviate the need for surgical biopsy. For a comprehensive discussion of lung biopsy in the ICU setting the reader is referred to prior editions of this textbook [50].

Lung Biopsy procedures can be grouped into two main categories: invasive, open surgical procedures (e.g., open thoracotomy lung biopsy and video-assisted thoracoscopic (VATS) lung biopsy) and semi-invasive, closed nonsurgical procedures (e.g., percutaneous transthoracic needle biopsy under fluoroscopic, ultrasound, or more commonly computed tomography (CT) guidance; transbronchial lung biopsy; and the more recently described, transbronchial cryobiopsy). In the setting of localized or diffuse parenchymal pulmonary disease, many factors are considered when developing a diagnostic plan, including the history of a probable inciting event (e.g., ARDS), the patient’s immune status, the severity of disease, the pace of the presentation, the timing of the diagnostic intervention, the diagnostic yield, the likelihood that the results obtained will alter management (the concept of a “contributive result”) [51], the risks of bleeding or other complications, and the availability of local expertise for performing the various types of procedures. Prior to proceeding with lung biopsy one should strongly consider the utilization and contribution of BAL (bronchoalveolar lavage) when specimens are sent for culture, viral PCR (polymerase chain reaction), cell counts, and cytology. In many situations, BAL, without tissue biopsy, is the least invasive and safest sampling method (even in a patient with a bleeding diathesis) and, when combined with the probable clinical diagnosis, is completely adequate and sufficient for directing appropriate therapy. Of course, when considering various lung biopsy approaches, contraindications must be taken into account (see Table 182.4) and also the likelihood that a particular method of biopsy can establish or rule out a given diagnosis based on pretest probability (see Table 182.5).

| TABLE 182.4 Contraindications and Relative Contraindications to Lung Biopsy [1–5] |
|----------------------------------|----------------------------------|
| Open thoracotomy biopsy          | Contraindication                 |
|                                  | Too ill to undergo general anesthesia |
| Thorascopic lung biopsy          |                                  |
Contraindications
Too ill to undergo general anesthesia
Extensive pleural adhesions
Uncorrectable coagulopathy
Postpneumonectomy patient
Severe pulmonary hypertension

Relative contraindications
Inability to place a double-lumen endotracheal tube
Inability to tolerate single lung ventilation

Closed biopsy
Contraindications
Uncorrectable coagulopathy (including uremia)\(^a\)
Unstable cardiovascular status
Severe hypoxia likely to worsen during bronchoscopy
Inadequately trained bronchoscopist
Poor patient cooperation

Relative Contraindications
Recent myocardial infarction or unstable angina
Adjacent vascular abnormalities
Positive-pressure ventilation
Cavitating lesions (especially with air-fluid levels, or >10 cm diameter)
Severe pulmonary hypertension
Adjacent emphysematous lung disease
Suspected echinococcal disease
Uncontrollable cough

\(^a\)Bronchoalveolar lavage can be performed with relative safety in patients with thrombocytopenia.

TABLE 182.5 Potentially High Yielding Biopsy Procedures for a Variety of Underlying Disease Processes

Bronchoalveolar lavage
Infections (PCP, mycobacteria, and endemic fungal)
Alveolar proteinosis
Alveolar hemorrhage
Acute eosinophilic pneumonia
Lung cancer
Lymphoma
Exogenous lipid pneumonia

Transbronchial needle aspiration
Lung cancer
Lymphoma
Infections (endemic fungi, mycobacteria, and nocardia)

Bronchial brush biopsy
Lung cancer
Metastatic cancers

Transbronchial lung biopsy
Sarcoidosis
Lymphangitic carcinomatosis
Alveolar proteinosis
Lung cancer
Chronic eosinophilic pneumonia
Amyloidosis
Lymphocytic interstitial pneumonia
Cryptogenic organizing pneumonia
Hypersensitivity pneumonitis
Invasive aspergillosis

Open lung biopsy or video-assisted thoracoscopic biopsy
Pulmonary capillaritis (vasculitides)
Diffuse alveolar damage
Idiopathic pulmonary fibrosis
Nonspecific interstitial pneumonitis
Inorganic pneumoconiosis

PCP, Pneumocystis pneumonia.

Open lung biopsy (OLB) has the advantage of providing a large tissue sample for pathology and is sometimes performed for critically ill
patients, especially those with ARDS featuring extensive lung infiltration of uncertain etiology. Two recent systematic reviews on the role of OLB of critically ill patients have shed light on its performance characteristics and utility. Libby and colleagues found that OLB in ARDS provided a specific diagnosis in 84% of patients and led to a change in management in 73% of cases. Moreover, there was acceptable mortality (43%, rarely because of the OLB itself) and morbidity (complication rate of 22% with PAL being the most common complication) [52]. Wong and colleagues combined the Libby study with other case series and found that OLB had a more modest diagnostic yield of only 54%. They additionally reported that the most common diagnoses made by OLB were fibrosis/pneumonitis and infection [53]. Therapeutic changes did occur for most (78%) of the patients and complication rates were similar to the Libby study. VATS may also be utilized as a biopsy technique for ARDS and has been reported to have yields and complications similar to OLB. However, severely critically ill patients and moribund patients may not tolerate VATS, a surgical procedure that requires single lung ventilation during general anesthesia.

Transbronchial lung biopsy via a flexible bronchoscope is an important biopsy technique because it may obviate the need for OLB in certain circumstances (e.g., immunocompromised patients or lung transplant patients when graft rejection and infection are considered). As stated above, a decision to proceed with TBBx (and OLB) should only be taken after careful risk-benefit analysis of inherent limitations and potential complications (TBBx bleeding risk of 1% to 4% and risk of pneumothorax up to 25% of mechanically ventilated patients) [54]. Fluoroscopy can increase yield and possibly safety and is generally recommended, especially when targeting focal parenchymal disease which is difficult in the ICU, resource-limited settings, and is associated with radiation exposure. The diagnostic yield of TBBx is limited by the size of the specimens obtained (1 to 3 mm), crush artifact, and sampling error. TBBx results are frequently nonspecific and, therefore, the technique has a limited role for the assessment of most idiopathic interstitial pneumonias and vasculitides. However, it does have significant yield for diseases such as sarcoidosis, eosinophilic pneumonia, various infections, and lymphangitic carcinomatosis.

Small sample size and tissue artifacts associated with TBBx create considerable problems in interpreting pathologic specimens and thus limit its diagnostic accuracy in many settings. In order to obtain larger tissue samples and avoid artifact, proceduralists and investigators have recently explored flexible bronchoscopic transbronchial cryobiopsy to obtain lung specimens. The technique of transbronchial cryobiopsy has been thoroughly described elsewhere [55]. Results from various case series have demonstrated that large tissue specimens can be obtained
(median size three to five times greater than TBBx) and these have preserved histologic characteristics, often free of artifacts. When correlated with clinical and radiologic findings, this technique has allowed the diagnosis of interstitial pneumonias such as NSIP (nonspecific interstitial pneumonia) and UIP (usual interstitial pneumonia), producing diagnostic yields as high as 70% to 80%. Complications include pneumothorax in up to 23% of cases and minor bleeding that is readily controlled. More severe bleeding sometimes requires placement of an endobronchial blocker. The future is promising for this newer technique and we await further studies that are specific to the critical care setting.
CONCLUSIONS

The still growing specialty of IP deals with many complex airway and pleural diagnoses and features a variety of diagnostic and therapeutic bronchoscopic and pleural procedures that are helpful in the ICU setting. Given the complexities of the critically ill patient population, a multidisciplinary approach to clinical management is ideal. One key to success is a close collaboration among intensivists; IP physicians; thoracic surgeons; ENT specialists; radiation and medical oncologists; and interventional radiologists.
REFERENCES

INTRODUCTION

Although its precise function is complex and incompletely understood, sleep is considered a vital process necessary for physical, emotional, and psychologic well-being and survival. In the intensive care unit (ICU) setting, critically ill patients often experience poor sleep quality owing to underlying baseline comorbidities, severe illness, loud noises, bright lights, care-related disturbances, and noxious medications. Although the contribution of poor sleep to the ICU recovery process remains largely unknown, interventions to improve sleep have garnered significant attention as part of recent efforts to improve outcomes during and following critical illness. This chapter provides a summary of current knowledge surrounding sleep in the ICU, including an overview of normal sleep, causes and potential consequences of sleep disruption in the ICU, and strategies to improve sleep for critically ill patients.
OVERVIEW OF NORMAL ADULT SLEEP

Sleep Architecture

A basic knowledge of normal adult sleep physiology is necessary to appropriately understand and improve sleep in the ICU setting. Adults are recommended to obtain 7 to 9 hours of consolidated sleep during each 24-hour cycle [1]. Sleep is divided into non-rapid eye movement (NREM) and rapid eye movement (REM) stages, which alternate over four to six 90- to 100-minute cycles across the sleep period (Fig. 183.1). NREM is comprised of N1, N2, and N3 stages, which account for 2% to 5%, 45% to 55%, and 13% to 24% of the sleep period, respectively, whereas REM comprises 20% to 25%. In general, stages N1 and N2 are “lighter” than stage N3, which is also known as “slow wave” or “deep” sleep and is believed to play a key role in the body’s restorative processes. REM, on the other hand, is characterized by muscle atonia but involves autonomic variability and substantial brain activity, including dreaming. Although NREM predominates in the first third of the sleep period and tends to occur soon after sleep onset, most REM occurs in the latter half of the sleep period.

![Figure 183.1](image) One night hypnogram of normal adult sleep, demonstrating typical sleep stage transitions.

Circadian Rhythms

Achieving a normal duration and pattern of sleep relies on individual
factors such as age, comorbid conditions, intrinsic sleep–wake cycle, volitional control of sleep duration, and drugs, along with environmental factors such as ambient temperature, noise, and light [2]. The sleep–wake cycle is regulated through two complementary processes, the sleep homeostat and circadian pacemaker. The sleep homeostat, or process S, dictates sleepiness and is influenced by buildup of melatonin and the neurotransmitter adenosine, the end product of ATP metabolism. Process S is similar to thirst: the longer you are without sleep, the sleepier you become. As an opposing process, the circadian pacemaker, or process C, dictates wakefulness and is largely synchronized to environmental light–associated suppression of melatonin release from the pineal gland. In nocturnal sleepers, melatonin secretion occurs in the absence of light, between 9 p.m. and 3 a.m., with lowest values between 7 a.m. and 9 a.m. [3].

Physiologic Processes During Sleep

During sleep, a complex interplay of physiologic processes occur, which are believed to play a fundamental role in growth and homeostasis. The physiologic processes most relevant for critically ill patients are discussed here.

Thermoregulation

Sleep and circadian rhythms play an integral role in body temperature and thermoregulation. In healthy adults, body temperature peaks late in the day, falls during sleep, nadirs late in sleep, and rises before awakening. During NREM, temperature sensitivity decreases, whereas poikilothermia (body temperature variation based on surroundings) and a loss of compensatory responses (i.e., sweating and shivering) occur during REM.

Respiratory Processes

N1 sleep is characterized by decreased respiratory drive and muscle activity, irregular breathing, and increased upper airway collapsibility. During N2 and N3, respiratory rate and tidal volume stabilize whereas minute ventilation falls, resulting in a rise in arterial PaCO$_2$ of 4 to 6 mm Hg and concomitant drop in pH of 0.03 to 0.05 units. This hypoventilation is believed to occur in the setting of decreased central ventilatory drive, upper airway muscle relaxation, and increased airway
Cardiovascular Processes

Alterations of blood flow and electrical activity that occur during sleep can increase one’s risk of life-threatening cardiovascular events, especially in those with diminished cardiorespiratory reserve [4]. During NREM, increased parasympathetic tone leads to a drop in blood pressure, heart rate, and systemic vascular resistance. Alternatively, during REM, a relative increase in sympathetic tone leads to increased (up to 35%) blood pressure and heart rate [4]. Bursts of vagal activity during REM can also potentiate sinus pauses and bradycardia.

Endocrine Processes

Growth hormone (GH), prolactin, cortisol, and thyroid-stimulating hormone (TSH) undergo fluctuations during the sleep–wake cycle [1] (Fig. 183.2). GH and prolactin, cell differentiation and proliferation hormones possibly involved in preservation of muscle mass and immune function during critical illness, peak during early and late sleep, respectively, and remain at low levels during wakefulness. More specifically, GH secretion has been shown to correlate with depth of sleep and is therefore highest during N3 [5]. Alternatively, cortisol, a key hormone involved in glucose metabolism, stress, and wound healing, follows a diurnal cycle, rising in the morning and falling toward bedtime. TSH secretion follows a similar circadian pattern, peaking before sleep onset and falling during sleep.

**FIGURE 183.2** Hormone levels in healthy adults maintaining standard sleep–wake cycles, activities, and meal times. Lines represent levels of melatonin, cortisol, growth hormone, prolactin, and thyroid-stimulating hormone across the sleep–wake cycle. A typical sleep period is represented by the shaded rectangular box.
(From Knauert M: Sleep and sleep disordered breathing in hospitalized patients. Semin Respir Crit Care Med 35:582, 2014, with permission).
A typical night in an ICU is characterized by a busy whirlwind of beeping alarms, loud voices, bright lights, and visits from providers to administer medications, gather vital signs, draw blood, perform X-rays, and perform routing assessments. As a consequence, sleep suffers, leading patients to list poor sleep quality as an important cause of anxiety and stress in the ICU and among the worst memories of their ICU experience [4].

Sleep Architecture of the Critically Ill

Studies of medical and surgical ICU populations have demonstrated that mechanically and nonmechanically ventilated critically ill patients generally experience exceptionally poor sleep quality as compared to healthy adults. Regardless of sedation or mechanical ventilation status, critically ill patients experience marked variability in sleep duration, with reported ranges of 3.6 to 6.2 hours per day [6–9] in some studies and 7.0 to 10.4 hours in others [10–12]. Whether patients experience short- or long duration of sleep, numerous investigations involving polysomnography (PSG) have demonstrated that sleep in the ICU is characterized by a predominance of N1 and N2, reduced or near absent N3 and REM, and marked fragmentation, with over 50% of sleep occurring during daytime hours [1] (Fig. 183.3). In a notable study involving polysomnographic recordings from 22 critically ill patients, of whom 20 were mechanically ventilated, patients averaged 41 ± 28 episodes of sleep per 24-hour period, each averaging 15 ± 9 minutes, highlighting the profound level of sleep fragmentation in this population [12].
Sleep Measurement in the ICU

Measuring sleep in the ICU is exceedingly challenging. Whether limited by logistical, environmental, or patient-related factors, instrument reliability, or cost, existing challenges in measuring sleep accurately and on a large-scale remain a key barrier hindering efforts to understand and improve sleep in the ICU setting [13].

Polysomnography

PSG, the most widely used mode of sleep measurement, involves simultaneous electroencephalogram (EEG), electromyogram (EMG), and electrooculogram (EOG) recordings. Although PSG is the gold standard for sleep measurement, its large-scale use in the ICU is challenging because it is costly, laborious, and requires bulky equipment, skilled technicians, and interpretation by a sleep expert. Moreover, interpretation of PSG is especially challenging in the presence of common ICU medications and illnesses such as sepsis, shock, hepatic encephalopathy, and renal failure [1,4,14]. More recently, a multisite investigation involving continuous PSG recordings in 37 mechanically ventilated patients revealed EEG recordings suggestive of sleep despite patients being interactive and awake, and others suggesting wakefulness despite patients being comatose [15]. Moreover, 36 of 37 patients, and 85% of recorded EEG data, demonstrated monotonous, atypical tracings uncharacteristic of conventional sleep stages or sleep/wake transitions, highlighting the challenges of interpreting PSG recordings and applying existing PSG scoring systems to the ICU population. Additionally, unattended PSG, which is likely required for large-scale ICU-based studies, was recently shown in a medical ICU population to be infeasible, because 26 of 28 (93%) patients were unable to tolerate PSG for 24 hours owing to reasons such as discomfort, mobility limitation, and, ironically,
the PSG devices themselves causing inability to sleep [9]. Hence, PSG is impractical for large-scale ICU sleep investigations and is therefore discouraged [13].

**Actigraphy**

Actigraphy, which involves accelerometer-based sleep estimation using a wristwatch-like interface, is a well-established research instrument. As compared to PSG, actigraphy is affordable, involves a comfortable interface, is practical for prolonged and large-scale use, and allows for assessments of physical activity unavailable with other sleep measurement modalities [16–19]. Although actigraphy seems ideal for sleep estimation, its use for the critically ill is recommended cautiously out of concern for overestimation of sleep and underestimation of wakefulness in the setting of limited mobility [20] because of common ICU factors such as sedation, restraints, neuromuscular weakness, or severe illness. Moreover, actigraphy measurement in the ICU has been limited to studies that were small in size [20–30], involved recording times of <24 hours [16,20,21,31], or enrolled primarily mechanically ventilated and/or sedated patients [17,20,21,32,33]. Nevertheless, as efforts to promote sleep, minimize sedation, and mobilize patients in the ICU setting grow [34], actigraphy may be utilized to assess the effect of ICU-based interventions.

**Bispectral Index**

Bispectral index (BIS) involves a single forehead sensor containing multiple EEG electrodes, whose signals are processed to provide a 0 to 100 integer value corresponding to level of consciousness. Often used to assess depth of anesthesia during surgery, BIS can evaluate sleep depth, similar to PSG, and provide continuous, unsupervised recordings using a simple interface, similar to actigraphy. Although BIS poses a potentially attractive option for sleep evaluation in the ICU, its interpretation is complicated by variability and overlap of cutoffs for sleep stages and sedated states [4,35]. Moreover, similar to PSG [9], BIS in the ICU is susceptible to electrode detachment and artifact with subject movement [35], thus complicating its potential use for continuous, unattended recordings on a large scale.

**Subjective Measures of Sleep**

Subjective sleep measurement, whether by patients or their proxies, represents the most practical option for evaluating patient sleep in the ICU. The most commonly used instruments in the ICU are the Richards-
Campbell Sleep Questionnaire (RCSQ) [36,37] and Verran/Snyder-Halpern Sleep Scale [38,39], which both involve 5- and 14-item visual analogue scales, respectively, assessing various characteristics of sleep. Although both instruments are reliable, only the RCSQ has been validated against PSG for a critically ill population [37,39]. Nevertheless, both instruments have been utilized extensively as an endpoint of ICU-based interventions to improve sleep [40–45]. Despite their low cost and ease of use, these instruments are potentially limited by recall bias, rater fatigue across repeated daily assessments, noncompliance, impaired patient cognition or consciousness, and lack of daytime sleep ratings. Although bedside nurses may complete these instruments on their patients’ behalf [41,46,47], a recent interrater reliability study of the RCSQ demonstrated that nurses tend to overestimate patient sleep quality [48]. Hence, the use of nurse proxies to subjectively assess sleep in the ICU, whether by observation or validated instruments, must be performed with caution.

Causes of ICU Sleep Disruption

Noise

Whether attributed to staff conversations, alarms, ventilators, or nightly floor waxing, most ICUs are loud at all hours of the day (Fig. 183.4). Studies of both medical and surgical ICUs have demonstrated that noise levels frequently approach and exceed 80 decibels (dB) [8,12,49–56], the threshold necessary to maintain sleep, and far surpassing the 35 dB and 45 dB nighttime and daytime ICU limits outlined by the Environmental Protection Agency [1,4,14,18]. When correlated with PSG recordings, these loud noises have been attributed to 11% to 18% of sleep arousals and 17% to 24% of awakenings in critically ill patients [8,12,51,57].
Subjectively, patients in the ICU consistently report staff conversations and alarms as the most disruptive noises affecting sleep [8,58]. When measured, these factors comprised 26% and 31%, respectively, of ICU noises ≥75 dB in an observational study [59], and 57% and 30% in a detailed soundscape analysis [54]. Interestingly, a recent investigation commented that the traditional ICU design, with closely spaced beds facing a central nurse station, strongly contributes to noise pollution [60]. This study also noted that although staff conversations were loudest in the rooms of the sickest patients, they were often unrelated to patient care and held directly over patients under the assumption that sedation rendered patients unaware of their surroundings. These findings highlight potentially important and underrecognized design and behavioral issues worth considering during ICU-based sleep improvement efforts.

**Light and Melatonin**

In addition to promoting well-being, improving mood, and possibly preventing ICU delirium [61], light plays a key role in synchronizing circadian rhythms, and therefore in regulating sleep and wake. When light levels falls below 100 lux (normal indoor light ~180 lux), melatonin is secreted from the pineal gland, promoting sleep. Conversely, in the presence of light, melatonin secretion is suppressed, promoting wakefulness. Moreover, light levels above 1,500 lux are considered sufficient to disrupt sleep. Although ICU-based studies are lacking on this topic, one study involving continuous light measurement of four ICUs demonstrated mean maximum nocturnal light levels of 128 to 1,445 lux, high enough to suppress melatonin release but below the threshold to disrupt sleep [53].

Melatonin, and melatonin supplementation in particular, has received recent attention [62]. Independent of light levels, impaired melatonin secretion has been described in patients with sepsis [63] and delirium [64,65], suggesting that factors other than light influence circadian rhythms in the critically ill. As small trials involving melatonin have demonstrated both positive [24,32] and negative [66] findings regarding improvements in ICU sleep quality, further research is needed in this area.
Patient Care Interactions

Although difficult to measure accurately, critically ill patients experience approximately 7.8 patient care interactions per hour during sleep [67] and 43 to 51 per night shift [68,69]. These interactions include care-related activities such as vital sign checks, blood draws, medication administration, radiographs, baths, wound care, respiratory care (e.g., suctioning and ventilator adjustments), and general assessments, along with care-unrelated activities such as family visitation. When correlated with PSG in one study, 20% of these activities precipitated a sleep arousal or awakening, accounting for 7% of all observed sleep disruptions [8]. These data are supported by patient reports that blood draws, vital sign checks, and nurse visits are the most disruptive ICU factors affecting sleep [41,58].

Efforts to minimize patient care interactions should involve engagement of staff to evaluate the timing and necessity of interactions during patient sleep. Although minimizing interactions with unstable patients is not feasible, a recent interventional study demonstrated that for more stable patients, engaged ICU staff were able to bundle closely scheduled orders and conduct baths earlier, resulting in less nighttime interactions [41,70].

Mechanical Ventilation

Mechanical ventilation, which is administered to roughly 40% of ICU patients [71], improves gas exchange during respiratory failure but can also affect sleep quality. In general, ICU patients receiving mechanical ventilation report worse sleep quality than their nonventilated counterparts [58], experiencing greater sleep fragmentation, lower sleep efficiency, and more sleep during daytime hours [10,72]. When quantified, patients receiving mechanical ventilation average 20 to 63 sleep arousals per hour [8–12], which can be precipitated by issues related to patient-ventilator synchrony, or by noxious factors associated with mechanical ventilation, such as suctioning, repositioning, ventilator alarms, physical restraints, provider assessments, and discomfort from endotracheal, nasogastric, or orogastric tubes.

The effect of ventilator mode on sleep quality has been studied extensively. In a study of 11 mechanically ventilated ICU patients receiving pressure support (PSV) and assist control (ACV) ventilator modes, PSV precipitated more central apneas and subsequent sleep arousals and awakenings per hour than ACV (79 ± 7 vs. 54 ± 7), in particular when PCO$_2$ levels dropped below the sleep-induced apnea threshold [73]. By adding dead space to the ventilator circuitry during PSV, the investigators observed a significant rise in PCO$_2$ and a
concomitant decline in central apneas and sleep disruptions. Adding to these findings, a study of 20 patients alternating between ASV and lower pressure PSV (6 cm H₂O) during sleep noted markedly increased wakefulness during PSV, but no central apneas [74]. Although this study suggested that mode and not level of support had a greater effect on sleep, a subsequent study of 15 patients alternating between ACV, clinician-adjusted PSV, and PSV that automatically adjusted to patient effort, compliance and end-tidal CO₂ demonstrated equally fragmented sleep with all three modes [51]. Moreover, 13 patients receiving PSV and proportional assist ventilation (PAV), which promotes patient-ventilator synchrony by delivering pressure support proportional to patient inspiratory effort, suggested improved sleep quality during PAV as compared to PSV [56]. However, as confirmed in another study of 17 patients [75], the authors noted that patients who were synchronous with PSV experienced similar sleep quality as during PAV. Finally, a study of 14 awake, nonsedated patients alternating between neutrally adjusted ventilator assist (NAVA) and PSV demonstrated reduced apneas, increased REM, and improved sleep quality during NAVA, as neuromechanical coupling during NAVA presumably improved patient-ventilator synchrony [57].

Synthesizing this literature, a recent meta-analysis of randomized controlled trials of interventions to improve sleep in the ICU revealed significantly improved sleep efficiency, but not sleep fragmentation, when comparing timed with spontaneous modes of ventilation [76]. As important limitations, the authors acknowledged the small sample size and single-site design of the included studies. Hence, until larger multisite trials are performed, practitioners should adopt an individualized approach to ventilator management during sleep, and consider use of less conventional ventilator modes to optimize patient-ventilator synchrony.

Although noninvasive ventilation (NIV) is administered frequently in the ICU and in the outpatient setting for sleep-disordered breathing (SDB), little is known regarding sleep during NIV in the ICU. Two investigations conducted by a single research group on 27 and 24 patients receiving NIV for hypercapnic respiratory failure demonstrated that, overall, whereas total sleep time and efficiency were low during NIV, the majority of sleep occurred at night, was of normal architecture, and was of higher duration and quality when compared to spontaneous breathing periods without NIV [77,78]. Interestingly, in the first study, patients
exhibiting worse sleep architecture were more likely to fail NIV, defined as requiring intubation or dying. These findings demonstrated that, in select patients, NIV was well tolerated during sleep and may aid in promoting sleep. Further research is needed to corroborate these findings.

**Medications**

Several common ICU medications can affect sleep architecture (Table 183.1). Sedative medication is frequently prescribed in the ICU, particularly for mechanically ventilated patients, to alleviate pain and anxiety and presumably to reduce agitation. Despite these properties, these agents can also affect sleep. For example, opioids such as fentanyl and morphine profoundly inhibit N3 and REM in addition to precipitating arousals and central apneas [4, 79]. Additionally, benzodiazepines such as lorazepam and midazolam, which are often co-administered with opioids, may lower sleep latency and increase N2 and total sleep time, but profoundly reduce N3 and REM sleep [4, 79]. Additionally, agents such as dexmedetomidine and propofol, which have gained popularity as less deliriogenic non-benzodiazepine sedative options [34, 80–82], may also contribute to fragmented sleep [83] but are considered less disruptive to sleep than benzodiazepines and opioids [80, 81, 84, 85]. Until research expands in this area, practitioners should aim to administer minimal or no sedation and perform daily interruptions of sedation, consistent with current guidelines [34], as a strategy to minimize sedation-related disruptions to sleep architecture.

A number of other common ICU medications can also affect sleep (Table 183.1). Vasopressor medications such as norepinephrine, dopamine, and phenylephrine may diminish N3 and REM sleep via sympathomimetic pathways. However, in critically ill patients with various types and degrees of shock, it is unclear to what extent these drugs penetrate the blood–brain barrier [79]. Additionally, patients receiving β-blockers can experience REM suppression and, subsequently, nightmares and insomnia; however, this effect is likely dependent on lipid solubility of the drug administered [79]. Immunosuppressive drugs such as corticosteroids, which are prescribed often including during asthma and chronic obstructive pulmonary disease (COPD) exacerbations, and tacrolimus and cyclosporine, which are common among transplantation patients, are also known to disrupt sleep and cause insomnia [86,87]. Finally, haloperidol and olanzapine, antipsychotics receiving attention for their possible role in ICU delirium prevention [88], may promote restorative sleep stages and, in one study, were recommended as part of a pharmacologic guideline to promote
Withdrawal from medications may also affect sleep in the ICU. Abrupt discontinuation of prolonged, high-dose opioid and benzodiazepine infusions may precipitate sleep disruptions and insomnia, lending further support to strategies for sedation minimization, daily sedation interruption, and gradual tapering of prolonged sedation [79]. Additionally, because antidepressant medications such as tricyclic antidepressants, selective serotonin reuptake inhibitors, and monoamine oxidase inhibitors are often held in the setting of critical illness, patients should be monitored closely for associated withdrawal reactions including insomnia, nightmares, and REM rebound [79]. Finally, withdrawal from alcohol, nicotine, and illicit drugs such as cannabis and amphetamines can lead to profound insomnia and sleep disruption, and, in extreme cases, delirium [79].

Finally, medications prescribed specifically for sleep in the ICU can both promote and impair sleep. “Z-drugs,” which include zolpidem, zopiclone, eszopiclone, and zaleplon are non-benzodiazepine γ-aminobutyric acid (GABA\textsubscript{A})-receptor agonists commonly used for insomnia. These drugs possess hypnotic properties similar to benzodiazepines, but, unlike benzodiazepines, bind different GABA\textsubscript{A} receptor subunits and have a shorter half-life, therefore disturbing sleep architecture minimally [89]. Although these drugs can promote restorative sleep, their use in sick, frail, or elderly ICU patients is recommended cautiously owing to risk of oversedation, delirium, and drug–drug interactions.

Additionally, various medications are prescribed off-label for sleep in the ICU setting. Trazodone, while being the most commonly prescribed medication for sleep in the US, is a sedating antidepressant studied little for insomnia and carrying adverse side effects including hypotension and anticholinergic syndrome. Additionally, antihistamines such as diphenhydramine and doxylamine, commonly found in over-the-counter sleep preparations, can be oversedating and deliriogenic, particularly among the elderly. Therefore, trazodone and antihistamines were not recommended for sleep by an expert NIH panel on chronic insomnia [90].

In summary, developing a pharmacologic strategy to optimize sleep in the ICU requires a detailed review of potential benefits, side effects, and drug–drug interactions of existing medications, and consideration of underlying withdrawal states. Given a lack of evidence supporting
pharmacologic strategies to promote sleep in the ICU, nonpharmacologic interventions and medication minimization (i.e., lowering sedation) should be considered as first-line therapies to promote sleep, before prescription of new medications.

**Illness**

A variety of factors related to existing and preexisting illness can affect ICU sleep quality. Although the sickest patients likely deserve and theoretically should experience the most restorative sleep, studies on the association of severity of illness and sleep architecture are limited. Additionally, for sepsis, acute respiratory distress syndrome, shock, renal failure, encephalopathy, and coma, EEG recordings are often markedly atypical, making sleep interpretation difficult [4,15]. Nevertheless, critically ill patients with sepsis have demonstrated perturbed melatonin levels, suggesting poorer sleep quality in this population [63].

A number of preexisting comorbidities can predispose patients to worse sleep quality in the ICU setting. For example, COPD, a common cause of respiratory failure in the ICU, is associated with insomnia, sleep arousals, and reduced total sleep time, N3 and REM [91]. Additionally, SDB, which includes obstructive sleep apnea (OSA) and central sleep apnea, Cheyne-Stokes respiration, and obesity hypoventilation syndrome, can markedly disrupt sleep. More specifically, OSA and Cheyne-Stokes respiration are often seen with congestive heart failure and stroke, comorbidities common in the critically ill [1].

Finally, critically ill patients often experience pain, which has been shown to contribute to arousals, sleep fragmentation, and reduced total sleep time [7,8]. Additionally, anxiety and stress regarding one’s illness or the ICU environment have been reported by patients to impair sleep [92].
A large body of research, primarily from healthy and noncritically ill patient populations, has described a constellation of physical and neuropsychologic disruptions that occur in the sleep-deprived state. Theoretically, sick and often frail individuals with organ dysfunction and diminished reserve, similar to those in the ICU, would be most susceptible to dramatic physiologic changes following even the smallest amounts of sleep loss. However, research has yet to corroborate this hypothesis. Nevertheless, an understanding of potential short- and long-term consequences of sleep loss may be helpful to better deal with complex clinical problems and target interventions to improve sleep in the ICU.

Cardiorespiratory Consequences
Among noncritically ill adults, sleep deprivation of 24 hours or more has been shown to result in diminished respiratory muscle strength (Forced expiratory volume in 1 second [FVC], and maximal inspiratory pressure), especially for those with COPD, along with increased respiratory muscle fatigability, a blunted hypercapnic ventilatory response, and increased upper airway collapsibility [4]. How these findings apply to critically ill patients has not been investigated, but suggest that poor sleep may impair the respiratory aspects of the ICU recovery process, especially for those receiving mechanical ventilation or with altered baseline respiratory dynamics.

From a cardiovascular standpoint, during sleep deprivation, a surge in sympathetic tone and catecholamine release can lead to blood pressure, heart rate lability, and an elevated risk of myocardial ischemia [4]. As another potential fascinating consequence during the recovery from illness and illness-associated sleep deprivation, “REM rebound” occurs because individuals repay sleep debt and specifically REM sleep, and is characterized by an increased amount of REM with its associated autonomic variability leading to irregular breathing, labile heart rate, and hypoxemia [11]. REM rebound may therefore increase the risk of hemodynamic instability, especially for those with compromised cardiorespiratory physiology. Whether these phenomena occur in critically ill patients is unknown.

Immunologic Consequences
It is a popular belief that proper sleep is necessary to prevent and fight infection. At an extreme level, animal studies have demonstrated that profound sleep deprivation leads to an immunocompromised state, with decreased lymphocytes, leukocytes, and spleen weight, followed by septicemia and death [4]. Although studies in humans have fortunately not produced similar results, they have instead yielded some more complex ones. For example, although multiple studies have demonstrated that sleep-deprived individuals have an attenuated response to vaccination and alterations in markers and modulators of immunity, these data are inconsistent and are not supported by microbiologic studies [4]. Additionally, sleep deprivation can suppress proliferation of T-helper cells and the release of interleukin 2 (IL-2), whereas triggering the proliferation of leukocytes, monocytes, and natural killer cells, and the release of tumor necrosis factor-α, interleukin 1 (IL-1), interleukin-6 (IL-6), intercellular adhesion molecule 1, E-selectin, and C-reactive protein [4]. Although notable, the mechanisms and implications surrounding these alterations are poorly understood and have not been studied in the critically ill.

**Metabolic and Endocrine Consequences**

For the body, sleep deprivation is a state of catabolism and stress, characterized by a rise in oxygen consumption (V\textsubscript{O\textsubscript{2}}) and carbon dioxide production (V\textsubscript{CO\textsubscript{2}}), and the release of cortisol and catecholamines [4]. Although similar responses have been seen in critically ill patients with sepsis [93,94], it is unknown to what degree ICU-related sleep disruption plays a role in these processes, or whether improved sleep may alleviate this vigorous response.

The thyroid axis, GH, and prolactin are also affected by sleep deprivation. During sleep deprivation, TSH, T\textsubscript{3}, and T\textsubscript{4} rise and GH and prolactin fall; however, interestingly, the opposite trends tend to occur during critical illness [4]. How these opposing processes interact in the setting of ICU-related sleep disruption is unknown, but poses an interesting avenue for research.

Finally, sleep restriction has been shown among healthy subjects to blunt insulin secretion, decrease sensitivity to insulin, and impair glucose regulation [4]. How these alterations impact the critically ill, who often develop hyperglycemia and suffer adverse consequences from it [95], is unclear, and represents another important area of investigation.
Mobility-Related Consequences

Prolonged immobilization is common during critical illness and contributes to short- and long-term physical, functional, and cognitive impairments, along with early death [96,97]. Hence, early mobilization of ICU patients is now widely recommended and has been shown to reduce delirium, length of stay, and mortality, while improving physical and functional outcomes [96,98,99]. Poor sleep quality in the ICU has been identified as a key modifiable barrier preventing these mobilization efforts [100], based on studies in noncritically ill populations demonstrating reduced energy, diminished activity levels, weakness, and physical disabilities following sleep deprivation [101–103]. As interest in ICU early mobilization continues to grow, it is likely that sleep will also gain attention and further motivate efforts to improve sleep.

Delirium and Other Consequences

Delirium affects up to 80% of critically ill patients and has been shown in numerous studies to be associated with devastating short- and long-term outcomes including prolonged mechanical ventilation and length of stay, cognitive and physical disability, and early death [104]. Because delirium and sleep deprivation share similar characteristics, such as inattention and mood disturbances, their association and potential overlap have received particular attention during efforts to understand and prevent delirium in the ICU [46,105]. Nevertheless, the true association of delirium and sleep remains unknown. Observational studies in this area have described greater mental status changes among medical–surgical patients experiencing the most nurse-observed sleep interruptions [106] and increased delirium incidence in patients reporting sleep deprivation after thoracic surgery [107]. Additionally, a study involving single-night PSG in 29 mechanically ventilated surgical ICU patients demonstrated higher incidence of delirium among patients experiencing <6% REM [108]. Although these studies established an important foundation, additional larger, multisite studies involving validated instruments for sleep and delirium are necessary to clearly evaluate the delirium–sleep association.

Additionally, a large and expanding body of literature has revealed that survivors of critical illness often experience disabling psychiatric, neurocognitive, and psychologic complications after intensive care, including depression [109], posttraumatic stress [110,111], anxiety [111,112], cognitive impairments [113,114], and impaired health-related quality of life (HRQOL) [115–118]. Similarly, the sleep-deprived state has been demonstrated in many studies to be associated with depressed mood, anxiety, and stress [119,120]; cognitive deficits [121,122]; and
reduced HRQOL [123]. Given that most of the sleep deprivation studies involved healthy subjects who overcame their deficits with recovery sleep, it is unclear what impact the acute and often prolonged sleep loss experienced by sick ICU patients would have on long-term outcomes. Because studies on this topic would be complicated by confounding factors related to critical illness and the challenges of measuring sleep in the ICU, investigations in this area should focus on whether interventions to improve sleep in the ICU can attenuate adverse psychiatric, neurocognitive, and psychologic outcomes following critical illness.
METHODS TO IMPROVE SLEEP IN THE INTENSIVE CARE UNIT

In its 2013 Clinical Practice Guidelines for Management of Pain, Agitation, and Delirium (PAD) in the ICU, the Society of Critical Care Medicine (SCCM) introduced “promoting sleep in adult ICU patients by optimizing patients’ environments, using strategies to control light and noise, clustering patient care activities, and decreasing stimuli at night to protect patients’ sleep cycles” as new guideline with a level 1C recommendation [34]. This recommendation was motivated by the hypothesized association of poor sleep with delirium in the ICU and, subsequently, by the association of delirium with adverse short- and long-term outcomes (see “Delirium and Other Consequences” section). Hence, in addition to sedation minimization and early mobilization, sleep promotion has established itself as a cornerstone of ICU delirium prevention efforts.

Efforts to promote sleep in the ICU should address patient- and ICU-level disruptors of sleep, such as noise, light, patient care interactions, patient-ventilator dyssynchrony, and discomfort from uncontrolled pain [124] or anxiety, while maintaining circadian rhythmicity during waking hours via provision of zeitgebers (circadian cues), such as ambient light and physical activity. Studies in a number of ICU settings have supported the feasibility of simple interventions such as environmental noise, light, and/or disturbance reduction [43,125–131], earplugs and/or eye masks [132–135], and relaxation techniques [40,131,136,137], and some have even demonstrated modest improvements of measures of sleep quality [40,43,126,128,137].

More recently, multidisciplinary, multi-intervention “bundled” approaches have been applied for sleep promotion in the ICU (Table 183.2), given the ease of performing multiple similar interventions simultaneously (i.e., turning off hallway and room lights, televisions, and alarms at the same time), low incremental costs of added interventions, and success of prior bundled interventions [138]. In particular, two larger studies demonstrated feasibility and efficacy of bundled ICU sleep promotion interventions, which resulted in improvements of normal mental status (i.e., less delirium and coma) [41,42]. Notably, one study also involved a pharmacologic guideline recommending medications to promote restorative sleep (i.e., zolpidem and haloperidol), while discouraging commonly prescribed medications (i.e., benzodiazepines, opioids, and antihistamines) known to impair sleep [41].

Regarding mechanical ventilation, although a recent small meta-analysis suggested that timed modes of ventilation may promote sleep better than spontaneous modes [76], the PAD guidelines deemed insufficient evidence to support particular modes of mechanical ventilation to promote sleep (see “Mechanical Ventilation” section). Finally, a few small studies (\(n \leq 32\) ICU patients) evaluating melatonin and melatonin receptor agonists (e.g., ramelteon) for sleep promotion suggested that these medications are safe to administer, but the studies were underpowered or not designed to demonstrate clinically meaningful improvements in sleep quality or other important ICU outcomes [24,32,66,139].

It should be emphasized that despite recent SCCM PAD guidelines highlighting the previously underrecognized issue of sleep in the ICU, no guidelines currently exist to specifically guide ICU sleep promotion strategies. Hence, as with most ICU-wide intervention efforts, to achieve buy-in and sustain a sleep promotion protocol, practitioners should consider an established implementation approach involving engagement of a multidisciplinary stakeholder team, identification of dedicated champions, evaluation of local implementation barriers, and development and evaluation of interventions unique to their ICU environment and patient population [70,140]. Continued research is needed to identify and address common barriers to ICU-based sleep improvement efforts and standardize a sleep improvement protocol for use across multiple ICU settings.

Disorders of Temperature Control, Part I: Hypothermia
MARY KATHRYN STEINER • RICHARD S. IRWIN

This chapter reviews the normal physiology of temperature regulation and the major hypothermic syndromes. Iatrogenic and intentional hypothermia are also reviewed. Three hyperthermic syndromes—heat stroke, malignant hyperthermia, and neuroleptic malignant syndrome—are reviewed in Chapter 185.

NORMAL PHYSIOLOGY OF TEMPERATURE REGULATION

The equilibrium between heat production and heat loss determines the body temperature. For healthy, resting individuals, this equilibrium is tightly regulated, producing an average oral temperature of 36.60°C ± 0.38°C [1]. Table 184.1 is a conversion chart of temperatures in Celsius to Fahrenheit. Small shifts of this temperature set point occur, with a normal diurnal variation producing a peak temperature usually near 6:00 p.m. Minute-to-minute changes in body temperature are quickly sensed, and appropriate changes are made in body heat production and loss to restore a normal balance.

Heat Production

In a neutral environment (28°C for humans), humans generate all net body heat from the energy released in the dissociation of high-energy bonds during the metabolism of dietary fats, proteins, and carbohydrates. At rest, the trunk and viscera supply 56% of the body heat, but, during exercise, up to 90% may be generated by the muscles. Although shivering or an increase in muscle tone may produce a fourfold rise in net heat production [2], vigorous exercise may cause a sixfold increase.

Heat Loss

Under usual environmental conditions, heat exchange with the environment takes the form of heat loss. Heat may be exchanged by radiation, conduction, convection, or evaporation [3–6]. Radiation exchange—the transfer of thermal energy between objects with no direct contact—accounts for 50% to 70% of heat lost by humans at rest in a neutral environment. Conduction (10% to 15% of heat loss) involves the direct exchange of heat with objects in direct contact with the body. Larger quantities of heat may be rapidly exchanged when the body is submerged in water; this is caused by the much greater thermal conductivity of water as compared with air. Convection involves the exchange of heat with the warmer or cooler molecules of air that pass by the skin. Heat exchange by this mechanism increases rapidly with greater temperature differences between the skin and the air and with rapid airflow (e.g., wind). Evaporative heat loss of humans occurs primarily through perspiration. Evaporation of sweat from the skin requires that energy be supplied by the skin, resulting in a net loss of heat from the body of 0.6 kcal per g of sweat absorbed. Unlike the other methods of
heat exchange, evaporation can exchange heat loss even when a warmer environment surrounds the skin. Therefore, evaporation is the major means by which the body prevents hyperthermia in a warm environment.

Temperature Control Systems

The anatomy and regulation of the system that controls the body temperature has been reviewed in-depth by several investigators [2–6], as outlined in the previous edition and are only briefly described here. Neurons that are directly responsive to temperature ascend from the skin, the deep viscera, and the spinal cord through the lateral spinothalamic tract to the preoptic anterior hypothalamus. When the hypothalamus perceives a temperature increase, it modulates autonomic tone to produce (a) an increase in evaporative heat loss through increased sweat output by the body’s 2.5 million sweat glands, (b) cutaneous vasodilation that allows direct flow of heat to the skin to increase convective and conductive heat losses, and (c) decreased muscle tone and activity to prevent any unnecessary heat production. When the hypothalamus perceives a temperature decrease, it modulates autonomic tone to cause (a) sweat production to cease or decrease, (b) cutaneous vasculature to constrict, and (c) muscle tone to increase involuntarily and shivering to begin. The immediate defense of thermoregulation is via the autonomic nervous system, whereas delayed control is mediated by the endocrine system. Prolonged exposure to cold stimulates the thyroid axis, leading to an increased metabolic rate.

The monoamines, baroreceptor data, hypothalamic calcium and sodium concentrations, and inflammatory cytokines (interleukin-1, interleukin-6, and tumor necrosis factor-α) are believed to be modulators of the anterior hypothalamic thermostat. They produce effects slowly, and they have little to do with the regulation of acute temperature changes.

Voluntary responses play an important role in thermoregulation. Humans may respond to thermal stress by (a) adding or removing clothes (affecting evaporative, conductive, and radiant heat exchange), (b) moving to a warmer or cooler climate, (c) changing the level of activity, and (d) changing posture. Impairment of voluntary control places an unnecessary stress on autonomic control mechanisms, thereby predisposing to an imbalance in heat exchange and a change in body temperature.

The ability to regulate temperature effectively declines with age [7,8], probably as a result of deterioration in sensory afferents. Although
younger individuals usually notice temperature changes as low as 0.8°C, older persons may not notice changes of up to 2.3°C. Moreover, because the sweat threshold increases and sweat volume decreases with age, an older individual may be more susceptible to hyperthermia than a younger person [9]. Old age may also be a liability for hypothermia because of (a) a lower basal metabolic rate, (b) a higher heat conductance owing to a decline in body mass, (c) a decrease in the heat generated by shivering owing to a smaller muscle mass, and (d) an inability to vasoconstrict cutaneous vessels in response to cold. In the elderly, restricted mobility or deterioration of cortical function can lead to a greater impact on the voluntary responses to temperature changes compared with the young.
UNINTENTIONAL HYPOTHERMIA

Hypothermia, defined as a core temperature less than 35°C, may occur at all ambient temperatures and in patients of all ages but more commonly among the elderly. The stage of hypothermia, defined by core temperature, has a large impact on both recognition and treatment. The most commonly used definitions are as follows [227,228]. Mild hypothermia is a core temperature of 32°C to 35°C, moderate hypothermia is a core temperature of 28°C to 32°C, and severe hypothermia is a core temperature below 28°C. In addition, some experts regard a temperature of <24°C or <20°C as profound hypothermia [229,230]. Because the clinical features of hypothermia differ among patients, and because core temperature measurement is imprecise, the recognition of each stage is more important than its exact boundaries. Prehospital personnel, while carefully measuring core temperatures, may also refer to the clinical staging scheme described by the International Commission for Mountain Emergency Medicine, or the “Swiss System” [229].

- Mild hypothermia I—normal mental status with shivering-estimated core temperature of 32°C to 35°C
- Moderate hypothermia II—altered mental status without shivering-core temperature of 28°C to 32°C
- Severe hypothermia III—unconscious-estimated core temperature of 24°C to 28°C
- Severe hypothermia IV—apparent death-estimated core temperature of 13.7°C to 24°C
- Death V—death as a result of irreversible hypothermia-estimated core temperature of <9°C to 13.7°C

Hypothermia often occurs within 24 hours of admission in more than 3% of intensive care unit admissions [10]. Hypothermia is a diagnosis that is frequently missed and underreported. When all data are reviewed, the overall mortality from hypothermia in the United States has been conservatively estimated at 30 deaths per 1 million population per year [11]. The mortality for treated hypothermia ranges from 12% [12] to 73% [13].

Causes and Pathogenesis

The most frequent causes of hypothermia appear to be exposure, use of depressant drugs, and hypoglycemia. Understanding the causes of
hypothermia (Table 184.2) and their pathogenesis enables one to develop a rational approach to treatment.

**Exposure to Cold**

Wet, wind, and exhaustion contribute to increased loss of body heat. Wet clothing loses 90% of its insulating value [14], rendering soaked individuals effectively nude. Exposure to rain or snow contributed greatly to the development of hypothermia in 15 of 23 incidents among hikers discussed in one review [14]. Convective heat loss because of wind may increase to more than five times baseline values, increasing with wind velocity [15]. Hikers with poor selection of clothing, campers who fail to seek appropriate shelter, or skiing in unfavorable weather can result in fatal hypothermia [15]. Victims of hypothermia display inappropriate behavior that worsens hypothermia. Up to 25% may remove their clothing and burrow, hiding under a bed or on a shelf [16]. Many quickly experience loss of coordination and then stupor or collapse. Death may occur within an hour of the onset of symptoms [15]. Immersion in water at a temperature colder than 24°C leads to extremely rapid heat loss. Core temperature drops at a rate proportional to the temperature of the water [17]. Although survival periods of 1 to 2 hours have been reported for individuals immersed in water at 0°C to 10°C, death may occur within minutes.

**Drugs**

Alcohol, phenothiazines, barbiturates, and paralytic agents frequently
produce hypothermia by depressing sensory afferents, the hypothalamus, or effector responses reducing centrally mediated vasoconstriction. Alcohol impairs the perception of cold, clouds the sensorium, and acts as a direct vasodilator [18,19]. Alcoholics are also thought to be more susceptible to exposure because of a state of relative starvation, increased conductive losses from decreased subcutaneous fat, and high levels of blood alcohol that potentially impair the metabolic response to hypothermia by decreasing blood sugar and increasing acidosis. Most sedative–hypnotic drugs cause hypothermia by inhibiting shivering and impairing voluntary control. Phenothiazines increase the threshold necessary to produce shivering and lead to hypothalamic depression [10]; barbiturates decrease effective shivering [20]. Paralytic agents used to suppress ventilation prevent shivering and eliminate all voluntary control mechanisms [21,22]. Unexplained hypothermia has resulted from the administration of common antibiotics, such as penicillin [23] and erythromycin [24]. Bromocriptine may cause hypothermia by altering central dopaminergic tone [25].

**Endocrine Dysfunction**

Diabetic ketoacidosis, hyperosmolar coma, and hypoglycemia are frequently reported causes of hypothermia [18]. In one survey, 20% of patients with blood glucose levels less than 60 mg per dL had temperatures of less than 35°C. Hypoglycemia lowers cerebral intracellular glucose concentrations and impairs hypothalamic function [26]. In acute hypoglycemia (e.g., insulin administration), hypothermia occurs as a result of peripheral vasodilation and sweating. At glucose concentrations of less than 45 mg per dL, subjects fail to perceive cold environments and fail to shiver [27]. This impairment appears transient because normal regulatory mechanisms and euthermaia may be restored when normal serum glucose levels are restored.

The prevalence of hypothyroidism in hypothermic patients ranges from 0% to 10%. Several patients with mild hypothyroidism have been safely rewarmed to euthermaia without administration of exogenous thyroid hormone. In contrast, myxedema coma, a rare presentation of hypothyroidism, is associated with subnormal temperatures in 82% of cases [28]. It has a high mortality if not treated with exogenous thyroxine. Myxedema coma occurs most frequently among middle-aged to older women, and more than 90% of cases occur in winter [28]. Severe hypothermia with temperatures less than 30°C occurs in 15% of patients [28]. Coma arises because of a cerebral thyroxine deficiency. Hypothermia then results from a combination of loss of voluntary control mechanisms, from stupor or coma, decreased calorigenesis from thyroid deficiency, and decreased shivering, presumably from impaired
hypothalamic regulation [28,29].

Panhypopituitarism and adrenal insufficiency are also rare causes of hypothermia. Unless profound insufficiency exists, these conditions rarely produce significant hypothermia in the absence of some other insults to the thermoregulatory system.

Central Nervous System Disorders

Diseases such as stroke, primary and metastatic brain tumors, luetic gliosis, and sarcoidosis may produce hypothermia by direct anatomic impingement on the hypothalamus [30,31]. Metabolic derangements from carbon monoxide poisoning or thiamine deficiency (Wernicke–Korsakoff syndrome) can also produce hypothermia by affecting the hypothalamus [32–37]. Patients with anorexia nervosa have been shown to have multiple hypothalamic abnormalities, resulting in the lack of shivering and vasoconstriction and a rapid drop in core temperature when they are exposed to cold [38]. Shapiro syndrome has been reported to cause spontaneous periodic hypothermia by an unclear mechanism [20,39]. Several patients with multiple sclerosis have experienced transient hypothermia with flares of their neuropathy, suggesting the presence of hypothalamic plaques [40].

Spinal Cord Transection

Acute spinal cord injury disrupts autonomic pathways, such as skin and core temperature afferents. In addition, they develop a reduced body muscle mass, resulting in the inability to shiver effectively, loss of cold-induced reflex vasoconstriction responses, and immobility [41–43].

Skin Disorders

Skin disorders characterized by vasodilatation or increased transepithelial water loss may lead to hypothermia. Inappropriate conductive and convective heat losses in psoriasis, ichthyosis, and erythroderma have been shown to be associated with increased evaporative losses of up to 3 L per day [44,49]. Patients with extensive third-degree burns have been reported to have an even larger evaporative heat loss, losing up to 6 L fluid. When an additional cause of hypothermia is present, these patients may be in danger of severe drops in temperature. Heat loss and caloric requirements can be decreased dramatically by covering the skin with impermeable membranes to decrease evaporative losses [50–52].
Debility

Case reports suggest that hypothermia may occur in patients with debilitating illnesses, such as Hodgkin disease [49]; systemic lupus erythematosus [50,51]; and severe cardiac, renal, hepatic, or septic failure. Most debilitated patients are also compromised by some degree of immobility or decreased voluntary control.

Trauma

Trauma patients often are hypothermic [52,53] because of multiple insults to the thermoregulatory system [53]. In patients with moderately elevated injury severity scores, during the first day of hospitalization, 42% experience hypothermia, with 13% having temperatures less than 32°C [52]. The presence of shock [52] and massive transfusion [53] significantly contributed to the development of hypothermia in these patients.

Pathophysiology

Profound metabolic alterations occur in every organ system in response to a core temperature less than 35°C. Metabolic changes that appear to be temperature dependent occur in two phases: shivering (35°C to 30°C) and nonshivering (less than 30°C).

Shivering is characterized by intense energy production from the breakdown of stored body fuels. It involves an increase in muscle tone and rhythmic contraction of small and large muscle groups. In different patient populations with different measurement techniques, heat production has been shown to increase by four times the normal amount [54], oxygen consumption by two to five times, and metabolic rate by six times [55]. Central pooling of blood resulting from peripheral vasoconstriction may raise central venous pressure and slightly elevate cardiac output. Because cardiac output remains relatively close to normal and oxygen demand increases dramatically, mixed venous oxygen saturation decreases [56]. Hepatic and muscular glycogenolysis may cause blood sugar levels to rise, which is not seen in starved or exhausted patients or those with prolonged hypothermia [57,58]. The catabolism of fat increases the serum levels of glycerol, nonesterified fatty acids, and ketones. Anaerobic metabolism causes a rise in lactate levels, and levels as high as 25.2 mmol per L have been reported [59]. The metabolic acidosis induced by this intense catabolism is compensated for the most part by the increased metabolism of lactate in the liver and increased minute ventilation [58]. Cortisol levels rise [13]. Most of these metabolic changes peak near 34°C or 35°C and become much less pronounced near
the temperature of 30°C.

As core temperature falls toward 30°C, shivering nearly ceases and metabolism slows down dramatically. Near 30°C, metabolic rate approaches basal levels \[60\], and it may be half basal value by 28°C \[55\]. As shivering and metabolism slow down, oxygen consumption declines. At 30°C, oxygen consumption decreases to approximately 75% of basal value \[60\]; at 26°C to 35% to 53%; and at 20°C to only 25% of basal value. This profound decrease in metabolism is reflected by changes in every organ system (Table 184.3).

Cardiovascular Function

Increasing degrees of hypothermia are associated with malignant arrhythmias, depressed cardiac function, and hypotension. A decrease in cardiac conductivity and automaticity \[61–63\] and an increase in the refractory period \[64,65\] begin during the shivering phase and progress as core temperature decreases. The electrocardiogram (ECG) of mild hypothermia may show bradycardia with prolongation of the PR, QRS, and QT intervals. Below 30°C, first-degree block is usual, and, at 20°C, third-degree block may be seen \[57,66\]. Below 33°C, the ECG commonly shows the characteristic J-point elevation (Fig. 184.1). As temperature drops below 25°C, the likelihood of appearance of J waves increases \[67,68\], most prominent in the mid-precordial and lateral precordial leads \[69\]. J waves may persist 12 to 24 hours after restoration of normal temperature \[70,71\].
FIGURE 184.1  The electrocardiographic changes of hypothermia. As temperature decreases (top to bottom), the rate slows down and the PR and QT intervals become prolonged. J waves (arrows) appear at a temperature less than 35°C and become prominent by a temperature near 25°C. The J wave initially is seen (top) as a widened QRS interval with a slight ST elevation at the J point.

Atrial fibrillation is common at temperatures of 34°C to 25°C, and ventricular fibrillation frequently occurs at temperatures less than 28°C. The incidence of ventricular fibrillation increases with physical stimulation of the heart and is associated with intracardiac temperature gradients of greater than 2°C [72]. Purkinje cells show marked decreases in excitability in the range of 14°C to 15°C [63], and asystole is common when core temperatures drop below 20°C.

Consequently, there is a gradual decrease in cardiac output. Systole may become extremely prolonged [73], greatly decreasing ejection fraction and aortic pressures. Ventricular compliance is severely reduced [74]. Output decreases to approximately 90% of normal at 30°C and may decrease rapidly at lower temperatures, with increasing bradycardia or arrhythmia. Regional blood flow is altered to preserve myocardial and cerebral perfusion [75]. Although blood pressure appears to be initially maintained by an increase in systemic vascular resistance (SVR) [76], systemic resistance decreases and hypotension is common [57] at temperatures less than 25°C. Oxygen demand usually decreases more rapidly than does cardiac output, causing mixed venous oxygen content
to increase as the nonshivering phase begins.

Pulmonary Function

Pulmonary mechanics and gas exchange appear to change little with hypothermia [57,77–79]. Although the ventilatory response to an elevation in carbon dioxide tension (PCO₂) may be blunted [77], there is no clear decrease in hypoxic drive [57]. As the increased oxygen demand and acidosis of the shivering phase decline, minute ventilation decreases. Tidal volume and respiratory rate decline at lower temperatures. At 25°C, respirations may be only 3 or 4 per minute [19]; at temperatures less than 24°C, respiration may cease [55]. Apnea is presumed to be secondary to failure of respiratory drive at a brainstem level.

Renal Function

As blood pressure decreases during the nonshivering phase, glomerular filtration rate (GFR) may decrease by 85% [57] and renal blood flow by 75%, without a significant change in urine production. Maintenance of a good urine output, despite decreases in blood pressure and GFR in hypothermia, has been termed cold diuresis. This results from a defect in tubular reabsorption. The urine may be extremely dilute, with an osmolarity of as low as 60 mOsm per L and a specific gravity of 1.002 [80]. The stimulus for this dilute diuresis may be the triggering of volume receptors as central volume increases with peripheral vasoconstriction [73], a relative insensitivity to antidiuretic hormone [71], or a direct suppression of antidiuretic hormone release [19]. Although kaliuresis and glycosuria may accompany the dilute diuresis, the net result for the patient is dehydration and a relatively hyperosmolar serum.

Neurologic Function

Hypothermic patients present with coma. Complete neurologic recovery has been described in hypothermic adults after 20 minutes of complete cardiac arrest [18] and up to 3.5 hours of cardiopulmonary resuscitation (CPR) [80]. The mechanism by which hypothermia produces a seemingly protective effect is not well understood, because it probably relates to a significant decrease in cerebral metabolism and a smaller injury by the no-reflow phenomenon [81], a mechanism whereby the brain is protected from injury until reperfusion.
Cerebral oxygen consumption decreases by approximately 55% for each 10°C decrease in temperature [82]. Cerebral blood flow decreases from 75% of normal at 30°C to only 20% of normal at 20°C [57]. The supply of nutrients and removal of wastes are adequate at these extremes given patient recovery and experimental evidence that the intracellular pH of brain tissue cooled to 20°C is unchanged even after 20 minutes of anoxia [83].

Visual [84,85] and auditory [86,87] evoked potentials demonstrate delayed latencies; latency increases as temperature decreases. The spectrum of electroencephalographic frequencies also changes with hypothermia. In healthy men cooled to 33°C by immersion, θ and β activities increased by 17% and α activity decreased by 34% compared with control values [85]. Electromyography during hypothermia has been reported to be normal [88].

**Hematologic Function**

Hypothermia affects white blood cells (WBCs), red blood cells, platelets, and perhaps coagulation mechanisms. The WBC count in mild hypothermia remains normal to slightly elevated and drops severely at temperatures lower than 28°C [89,90]. The hematocrit usually rises in hypothermic patients at a temperature of 30°C, in part, because of hemoconcentration from dehydration caused by cold diuresis and in part as a result of splenic contraction [91]. The increase in blood viscosity in hypothermic patients appears to be because of decreased deformability of the red cell membrane [92]. After intravascular volume and euthermia have been restored, a mild anemia may last up to 6 weeks. Bone marrow aspirates obtained from these patients show erythroid hypoplasia and increased ringed sideroblasts, suggesting a maturation arrest [93]. Platelet counts drop as temperature decreases, and prolongation of the bleeding time has been noted at 20°C [89]. The decrease in platelet count is thought to be secondary to hepatic or splenic sequestration.

No clear evidence indicates that a coagulopathy is associated with hypothermia. Deep venous thrombosis and disseminated intravascular coagulopathy (DIC) have been reported in hypothermic patients [33,94].

**Gastrointestinal Tract Function**

Ileus, pancreatitis, and hepatic dysfunction accompany hypothermia. Ileus is present at temperatures 30°C and lower. Subclinical pancreatitis appears to be common. Although patients usually lack symptoms of acute pancreatitis, more than half have amylase elevations greater than 550 S units and up to 80% of patients who die of hypothermia have evidence of pancreatitis at autopsy [95]. The relationship between alcohol use and
pancreatitis in these patients is unclear. Hepatic dysfunction occurs commonly and involves synthetic and detoxification abilities. Postmortem studies of patients who died from exposure-induced hypothermia commonly have gastric submucosal hemorrhage [96] and, to a lesser extent, duodenal ulceration and perforation [97].

### Endocrine Function

Hypothermia directly suppresses the release of insulin from the pancreas and increases resistance to insulin’s action in the periphery [98,99]. The blood glucose level rises in early hypothermia because of glycogenolysis and increased corticosteroid levels, and remains elevated because of a decreased concentration and the action of insulin. Elevations in blood glucose, however, are usually mild; only 9% of patients in one series had blood glucose levels higher than 200 mg per dL. The responses to thyroid-stimulating hormone (TSH) and adrenocorticotropic hormone appear blunted [57]. In hypothyroid patients, TSH increases in response to cold [100]. Corticosteroid levels vary, but rarely appear to be severely depressed [58,101,102]. Urinary catecholamine levels are increased threefold to sevenfold on average in hypothermic deaths compared with death owing to other causes [96].

### Immune Function

Infection is a major cause of death in hypothermic patients. Hypoperfusion increases the risk of bacterial invasion in ischemic regions of the skin and intestine. Pneumonia risk is increased as a result of central nervous system depression reducing the cough reflex, an increase in atelectasis because of decrease in tidal volume and minute ventilation, impaired killing of bacteria by pulmonary alveolar macrophages, and the severity of cold-induced granulocytopenia [90,103]. Evidence from hypothermic animals with induced sepsis indicates an impaired release of PMNs from the marrow [90], impaired phagocytosis, migration [105], and a decrease in the half-life for circulating PMNs during hypothermia [103], leading to delayed clearance of staphylococcal [104] and Gram-negative organisms from the blood. Ineffective clearance of organisms may permit a continued low-grade bacteremia [104]. The role of changes in antigen–antibody interactions, complement activation, and innate immune pathways that are known to be impaired by cold in vitro, has not been clearly defined in hypothermic patients. Wound healing is delayed in patients with mild perioperative hypothermia [106]. Cytokine production, for example, interleukin-6 may be delayed and prolonged [107]. Thus, the hypothermic host with temperature dependant compromised barrier functions is more susceptible to invasion by
pathogens and less equipped to defend itself when invasion occurs.

**Drug Clearance**

Little is known about the clearance of drugs in hypothermic adults. Complex interactions of reduced cardiac output, dehydration, slowed hepatic metabolism, decreased GFR, abnormal renal tubular filtration and reabsorption, and altered protein–drug dissociation constant alter the volume of distribution and total body clearance of many drugs [108].

**Diagnosis**

The diagnosis of hypothermia may be suggested by a history of exposure or immersion, clinical examination, and laboratory abnormalities. Elderly, alcoholic, diabetic, quadriparetic, or severely debilitated patients are at high risk of hypothermia. Signs of hypothermia vary with the patient’s temperature. Cool skin, muscle rigidity, shivering, and acrocyanosis are present for most noncomatose patients. In obtunded patients, myxedema-type facies have been reported [95,109]. Although mental status changes vary widely among patients, they follow a typical pattern: between 35°C and 32°C, the patient may be stuporous or confused; between 32°C and 27°C, the patient may be verbally responsive but incoherent; and, at temperatures less than 27°C, 83% of patients are comatose but able to respond purposefully to noxious stimuli [110]. Muscle tone remains increased after shivering stops. Reflexes remain normal until body temperature is lower than 27°C, when they become depressed and/or absent. Plantar reflexes may be upgoing. The pupillary reflex may be sluggish below 30°C and may become fixed at temperatures less than 27°C. ECG changes are almost always present.

In the absence of an accurate temperature reading, the ECG can be used to gauge the degree of hypothermia [67,69]. J waves become prominent as temperature decreases and, in the absence of a cerebrovascular accident, appear to be pathognomonic for hypothermia. Prolonged PR or QT intervals in the presence of muscle tremor artifact and bradycardia strongly suggest the diagnosis. Because of the increased solubility of carbon dioxide and oxygen, arterial blood gases reported at 37°C may show a value of partial pressure of oxygen (PaO₂) + PaCO₂ greater than 150 mm Hg on room air, a biochemical impossibility at euthermia. An elevated hematocrit, a good output of dilute urine with hypotension, ileus, and an elevated amylase are helpful but nonspecific
indicators of hypothermia.

Because the symptoms of hypothermia frequently mimic those of other disorders, the diagnosis may be missed unless there is a clear history of exposure or an accurate temperature reading is taken. Proper diagnosis depends on the use of a low-reading thermometer to determine core temperature. Electronic temperature probes that are accurate at low temperatures, can be used in several body sites, have a rapid response time, and can be left indwelling to provide online temperature readings during treatment.

The site for recording the temperature is important (see Chapter 27). Oral or nasopharyngeal temperatures may not reflect core temperature because of the influence of surrounding airflow. Bladder temperatures are commonly used and are accurate in mild-to-moderate hypothermia [111,112]. In patients with severe hypothermia, especially those requiring endotracheal intubation, an esophageal probe inserted into the lower one-third of the esophagus (about 24 cm below the larynx) provides a near approximation of cardiac temperature. Esophageal temperature is the most accurate method to track the progress of rewarming. Rectal probe readings may rise with peritoneal lavage or fall if adjacent to cold feces; esophageal probes not inserted into the lower third of the esophagus may read falsely high if heated humidified oxygen is used. Infrared tympanic thermometers and the so-called temporal artery thermometers are not accurate.

Bladder and rectal temperatures should not be used for critical patients during rewarming. Changes in rectal and bladder temperatures significantly lag behind core temperature changes during rewarming. Great vessel temperature can be measured using the thermistor on a Swan-Ganz catheter, but is highly affected by the infusion of heated fluids. During extracorporeal rewarming, bladder and pulmonary artery temperatures may increase faster than esophageal and rectal temperatures [112]. It may be helpful to monitor at least two core sites.

**Differential Diagnosis**

Clinical changes produced by hypothermia can mask and mimic other diseases. For example, rigidity of the cervical musculature, a rigid abdomen and absent bowel sounds, or shock and coma may be because of other diagnoses, and clinical judgment is required.

Deviations from the temperature–symptom relationship should suggest that the cause of a symptom may be other than hypothermia. For example, ventricular fibrillation or coma with a temperature higher than 30°C or shock with a low hematocrit or heme-positive stools, or hypoglycemia for relative tachycardia should alert the physician to suspect another diagnosis and pursue further diagnostic evaluations.
Relative hyperventilation implies an underlying organic acidosis (e.g., diabetic ketoacidosis or aspirin overdose), because CO₂ production should be decreased in moderate-to-severe hypothermia.

Certain medications directly or indirectly cause hypothermia, either by impairing thermoregulatory mechanisms, decreasing awareness of cold, or by clouding judgment.

Establishing a diagnosis of myocardial infarction, after vigorous resuscitation attempts, can be difficult. Creatine kinase, lactate dehydrogenase, and serum glutamic oxaloacetic acid transaminase values may be elevated because of hepatic hypoperfusion and presumed skeletal muscle damage. Elevations in creatinine kinase MB and BB fractions have been reported in hypothermic patients with no evidence of cerebral infarct [60]. ECG changes in hypothermia do not mimic those seen in myocardial infarction, and are thus more reliable.

The neurologic manifestations of hypothermia vary widely, but the level of consciousness should be consistent with the core temperature. If the level of the consciousness is not proportional to the degree of hypothermia, suspect a head injury, central nervous system infection, or overdose.

**Treatment**

With immediate appropriate treatment, mortality should be low. Accumulated statistics suggest that mortality varies with the severity of the underlying disease and the temperature at initial examination. The overall mortality in a series of city-dwelling hypothermic patients was 12%, but this increased to nearly 50% if a serious underlying disease was present [13]. In the same series of patients, mortality increased to 1.8% for each 1°C decrease in temperature on admission. Mortality was higher when hypothermia occurred indoors [113]. In healthy young mountain climbers, mortality was also found to vary with body core temperature on admission: mortality was 25% for temperatures higher than 32°C versus 66% for temperatures lower than 27°C [55]. Multivariate analyses indicated that the strongest predictors of mortality were prehospital cardiac arrest, low or absent blood pressure, elevated blood urea nitrogen, and the need for tracheal intubation or nasogastric tube placement in the emergency department [114]. The Mount Hood tragedy suggests that serum potassium levels greater than 10 mEq per L, fibrinogen less than 50 mg per dL, and ammonia greater than 350 μg per dL at the time of diagnosis predict very low survival probability [111]. Asphyxia caused by submersion resulting in severe hypothermia may be associated with up to a 95% mortality rate [115]. The higher survival rates in city-dwelling patients are believed to represent the benefits of immediately accessible care. Many experts believe that without
treatment, mortality for profound hypothermia may approach 100%.

Treatment should be aggressive. Functional survival in adults has been reported even after 6.5 hours of CPR [116]. Treatment includes initial field care and transport, stabilizing cardiopulmonary status, treating the cause of hypothermia, preventing the common complications of hypothermia, and rewarming.

**Initial Field Care and Transport**

Field management of hypothermia from exposure or immersion includes removal of wet clothes replacing with dry ones, and insulate from cold and wind with blankets. Sharing the body heat of another person in the same sleeping bag appears to offer no significant advantage [117]. Drinking hot drinks is not encouraged because it may increase hypothermia by producing peripheral vasodilation through a pharyngeal reflex [118]. Glucose drinks have been advocated, but recent work has shown that glycogen depletion does not impair shivering or rewarming [119].

The following precautions should be taken to transport the victim: transport in the supine position to prevent seizures from orthostatic hypotension [16], avoid rough handling owing to risk of ventricular fibrillation [74,118,119], cut clothing off, and carry the victim gently by a team of rescuers. A patient without a blood pressure or palpable pulse may already be in fibrillation and should be resuscitated until adequate ECG and pressure monitoring are available (see Chapters 27 and 28) [120].

**Stabilizing Cardiopulmonary Status**

Because early death from hypothermia is as a result of hypotension and arrhythmia, the goal of initial in-hospital management of hypothermic patients should be to achieve a safe, stable cardiopulmonary status. Shock among those with mild hypothermia is usually caused by the dehydration that results from cold diuresis; in more profound hypothermia, it may be cardiogenic. Fluid resuscitation should be attempted in all patients with hypothermic shock. Delivery of fluids through a central rather than a peripheral catheter is preferable for several reasons: vasoconstriction makes insertion of peripheral intravenous (IV) catheters difficult, vasoconstriction may impair delivery of peripherally injected medications, peripheral IV catheters may cause unnecessary damage to frostbitten extremities, and central catheter placement permits
monitoring of central venous pressure. Because most patients are hemoconcentrated and hyperosmolar, slightly hypotonic crystalloid fluids should be given. Whenever possible, all IV fluids should be warmed to at least room temperature before infusion. If fluid resuscitation fails, pressor agents should be administered. Although pressor agents increase the risk of ventricular fibrillation, they have been used safely in patients with hypothermia [120,121]. The use of arterial and central venous pressure monitors may help guide treatment. The increased risk of hemorrhage from hypothermia-induced thrombocytopenia and prolongation of bleeding times must, however, be considered when undertaking invasive procedures, such as central venous catheter placement or intubation.

The management of arrhythmias must be approached in a nontraditional manner because many pharmacologic agents, pacing efforts, and defibrillation attempts do not work in the hypothermic patient [122–124]. Because supraventricular arrhythmias and heart block generally resolve spontaneously on rewarming [68,79], therapy is usually unnecessary. Digitalis should be avoided because the efficacy of the drug is unclear in hypothermia, and toxicity increases as the patient is warmed [64]. Little is known regarding the efficacy of calcium channel blockers in treating supraventricular tachyarrhythmias in hypothermic patients.

For hypothermic patients experiencing ventricular fibrillation, procainamide has been of little help and lidocaine has been of only modest benefit [119]. Bretylium or amiodarone appears to be the drug of choice [118,125–127]. Electrical defibrillation should probably be attempted at least once, but it is unlikely to succeed until core temperature surpasses 30°C [18, 72,128]. The role of pacing in patients with fibrillation and asystole is unclear [64,129]. If other avenues of support are unavailable, however, pacing should be tried [130].

Acid–base status and oxygenation should be assessed immediately. Accurate assessment of acid–base status for hypothermic patients is complicated by several issues. First, arterial blood gases measured at 37°C produce different values of pHa and PaCO₂ than those exist in a patient at a lower temperature. Second, normal values for pHa and PaCO₂ also change with temperature. Third, body buffer systems respond differently at colder temperatures. When blood is drawn from a hypothermic patient and then rewarmed to and measured at 37°C, the solubility of carbon dioxide decreases, resulting in higher PaCO₂ and lower pHa values than actually exist [131].

Normal values for pHa and PaCO₂ also change with temperature. At a temperature of 20°C, a pHa of approximately 7.65 permits continued cellular function, and this value, not a pHa of 7.40, should be regarded as normal. Normal values for PaCO₂ are altered because of the higher
content of carbon dioxide in cooled blood, decreased rate of production of carbon dioxide, and slower rate of carbon dioxide elimination from relative alveolar hypoventilation. Respiratory exchange ratio values as low as 0.32 have been reported. On balance, these changes result in lower PaCO₂ values at colder temperatures.

Temperature changes the protein–drug dissociation constant of chemical reactions and reduces the ionization level of buffer proteins [131]. This produces a smaller effective protein buffer pool and places a greater reliance for buffering on the less efficient carbonic acid system. Because of this less effective buffering, acid–base disturbances that would be well tolerated at 37°C might be poorly tolerated at lower temperatures.

Because of a decrease in the solubility of oxygen on warming the blood to 37°C, arterial oxygen tension values reported at 37°C may be substantially higher than the actual value in colder patients. Therefore, PaO₂ values must be corrected for temperature, or the presence of significant hypoxemia may be overlooked. Several nomograms to permit correction exist [132,138–140]. For clinical purposes, the following formula can be used to correct PaO₂ for temperature: decrease the PaO₂ measured at 37°C by 7.2% for each degree that the patient’s temperature is less than 37°C.

Because acute respiratory distress syndrome may, and pneumonia [97] frequently does, accompany hypothermia, a chest radiograph should be obtained. In all, 90% to 100% oxygen should be administered until adequate oxygenation has been demonstrated. Oxygen saturation, after correction for temperature, should be maintained at greater than 90% to help prevent hypoxic damage. Stuporous or comatose patients should have prophylactic intubation to decrease the risk of aspiration pneumonia. Blind nasotracheal intubation may be required; orotracheal intubation may be difficult because of the rigidity of upper airway muscles [122]. If respiratory failure is evident on blood gas analysis, the trachea should be intubated and the lungs mechanically ventilated.

Experiences during hypothermic surgery and in the treatment of unintentional hypothermia indicate that the initial ventilator settings should be similar to those normally used at temperatures of 37°C [132,133] (see Chapter 166).

Treating the Cause of Hypothermia

Hypoglycemia is rapidly detected by a glucose test strip and confirmed by blood glucose value. As a result of the ineffective action of insulin at low temperatures and the relatively high serum osmolarity from water diuresis, serious and difficult-to-treat hyperosmolarity may result from
boluses of high concentrations of glucose [58,79]. Therefore, treatment with highly concentrated glucose solutions should be delayed until measure of the blood glucose has been obtained. Once hypoglycemia has been documented, 25 to 50 g glucose as a 50% dextrose solution is given to the patient. Some patients have been reported to shiver on correction of hypoglycemia and to correct their hypothermia rapidly.

Alcohol or sedative drug use or overdose is usually indicated by history and confirmed by toxicologic screening. No reports indicate adverse effects of naloxone in hypothermia; it should routinely be given if coma is present.

A thorough neurologic examination may suggest central nervous system or peripheral nervous system disease. If the patient has a history of trauma, the neck should be stabilized until a cervical spine radiograph has been obtained. Flaccid extremities suggest a cord or peripheral nerve injury. Cerebral edema secondary to tumor may be seen on funduscopic examination. Treatment with thiamine is benign and is given routinely for stuporous hypothermic patients until Wernicke–Korsakoff syndrome is ruled out. Thiamine is given with glucose, if hyperglycemia is absent, to decrease the chance of cerebral dysfunction. If the patient has Wernicke–Korsakoff encephalopathy, response to thiamine treatment may be seen within hours; if thiamine is not given, efforts to increase temperature may be futile [35,39]. Cyclic hypothermia is rarely fatal and responds to cyproheptadine, ephedrine, and naloxone [141,142].

Thyroid hormone is not given routinely to every patient with hypothermia because it is potentially harmful and hypothyroid coma is rare. In all cases of suspected myxedema, treatment with thyroid hormone is mandatory because it may be lifesaving. Conventional treatment of myxedema hypothermic coma begins with immediate IV administration of 0.2 to 0.5 mg thyroxine. If the patient has not clearly responded in 24 hours, this dose is repeated, and the patient is maintained on 0.05 to 0.10 mg thyroxine IV daily until clinically stable (see Chapter 142).

Debilitating diseases such as congestive heart failure, sepsis, hepatic, or renal failure should be treated in a conventional manner. For diabetic patients, insulin resistance increases rapidly below 30°C; insulin administration should be delayed when possible until the patient’s temperature is more than 30°C. If insulin is given during hypothermia, it must be administered IV because subcutaneous absorption is impaired by hypoperfusion. In addition, insulin should be given in small doses because its degradation may be delayed at low temperature and
cumulative doses may produce hypoglycemia and rebound hypothermia as the patient is warmed.

Preventing Common Complications

Early attention to the prevention, diagnosis, and treatment of diseases that are commonly associated with hypothermia may significantly reduce morbidity and mortality [143]. Diabetic patients who have hypothermia and infection have a particularly grave prognosis. In patients with diabetic ketoacidosis, the prevalence of hypothermia was four times higher in those with underlying infection and mortality was three times higher [144]. The possibility of infection should be carefully evaluated in diabetic patients with hypothermia, and early intervention with antibiotics should be considered.

Pneumonia is a common complication in hypothermic patients who survive the rewarming period. The incidence of pneumonia can probably be reduced by early intubation in stuporous or comatose patients to protect the airway, thereby minimizing aspiration. In addition, periodic hyperinflation [78], elevation of the head of the bed, and attention to periodic clearance of respiratory tract secretions may decrease the incidence of pneumonia in hypothermic patients. Antibiotics should only be given when infection is already likely to be present [143,145]. A study demonstrated that a low SVR in patients with mild-to-moderate hypothermia strongly indicates the presence of infection [76]. When SVR is low or diabetic ketoacidosis is present, we believe it is reasonable to give broad-spectrum antibiotic coverage for 24 to 48 hours pending results of respiratory tract cultures.

Because pancreatitis and ileus are both commonly associated with hypothermia, a nasogastric tube should be passed, a baseline amylase level should be obtained, and the patient should not be allowed to eat or drink until hypothermia has resolved, and pharyngeal swallowing function testing indicates minimal aspiration risk.

Prophylaxis of deep vein thrombosis (DVT) in patients with hypothermia is a difficult task. Subcutaneous heparin should not be used because it may be poorly absorbed for several days until skin function returns to normal. Pneumatic boots should not be placed on frostbitten extremities. Because of these concerns and because it is not clear that the risk of DVT from hypothermia outweighs that of systemic anticoagulation, we do not routinely recommend immediate prophylaxis for DVT. Because DIC has been reported, baseline clotting studies may be of value. DIC has occurred even in heparinized patients [146].

Acute tubular necrosis has been reported with hypothermia [66], but it is infrequent and probably results from shock and hypoxia, not as a direct action of hypothermia itself. Renal damage may be minimized by careful
cardiovascular support. Hypermagnesemia reduces temperatures in hypothermic patients with renal failure and should be avoided [147]. Hypophosphatemia may result from treatment [148]. Electrolyte levels may vary greatly during treatment.

In cases of exposure, frostbite frequently occurs on the ears, nose, face, penis, scrotum, and extremities. It may be painless and go unrecognized by the victim until he or she is rewarmed. Frostbite is detectable on physical examination because recently frozen tissue usually appears gray, white, or waxy. Soon after warming, the skin may become edematous, blister, or turn red or black because of hemorrhage or necrosis. The extent of damage and eschar formation is usually demarcated within 10 days. Limbs should be handled gently. Thawing frostbitten areas is best postponed until core temperatures have risen to normal and the patient’s condition is stable. It is best accomplished by immersion for 30 to 60 minutes in water heated to 38°C to 43°C. After thawing, whirlpool debridement, intra-arterial reserpine, and anticoagulation with heparin or dextran may be helpful. Amputation may be necessary but should always be delayed as long as possible to allow a clear demarcation of viable tissue [118].

Because of the risk of relapse, hypothermic patients require prolonged monitoring. Elderly patients who have had one episode of hypothermia may experience relapse and, in addition, may be at greater risk for future hypothermic episodes [149]. Any patient who has sustained severe hypothermia under conditions other than extreme exposure should be monitored closely for recurrent episodes.

Rewarming

Rewarming methods can be divided into three categories: passive external rewarming, active external rewarming, and active central rewarming.

Passive External Rewarming. Passive external rewarming is the least invasive and slowest rewarming technique. The patient is kept dry, sheltered from wind, and covered with blankets to decrease heat loss, thereby allowing thermogenesis to restore normal temperature. Temperature increase varies inversely with patient age; the average rate of temperature increase with this method is only 0.38°C per hour [60]. Passive rewarming is appropriate only when the patient’s core temperature is >30°C.

Active External Rewarming. Active external rewarming is the most controversial method. It involves raising the core temperature by heating the skin with hot blankets, electric heating pads, and hot water bottles;
circulating warmed air immediately adjacent to the skin [150,151]; or immersion in a tub of warm water. This method works [18,55,118,149,152] and has been successful in patients with temperatures as low as 17°C [153]. Initial reports [150,151] suggest that rewarming by covering the patient with a plastic blanket that contains tubes of circulating heated air is helpful for the mild hypothermia seen in the perioperative setting. Several studies have now documented that rewarming by the heated air method is safe and effective for moderate hypothermia of numerous etiologies. Mortality with active external rewarming appears to be higher than with passive or central rewarming methods [13]. This possible increase in mortality may be because of a (a) less accurate control over the rate of temperature increase, (b) increased risk of shock from warming the skin before the core, and (c) increased incidence of acidosis resulting from abrupt return of blood to the core from relatively hypoperfused areas. Treatment by immersion is impossible for patients who require continuous ECG and temperature monitoring, central venous access, and artificial ventilation and who are in imminent danger of shock or arrest. Experience with patients undergoing external rewarming suggests that aggressive hydration and central catheter monitoring are helpful [124].

**Active Central Rewarming.** The fastest and most invasive warming methods are those designed to permit active central rewarming. Although commercial Food and Drug Administration–approved warmers limit fluid warming to 40°C, heated IV crystalloid to temperatures as high as 65°C has been shown to be safe in animal trials [154]. Oxygen that has been humidified and heated to 40°C to 46°C is a safe [13,155] and effective [153] rewarming technique; it can be delivered by face mask or an endotracheal tube. Temperature must be monitored orally to ensure that inspired air does not exceed 46°C, or mucosal damage or burns might occur. Temperature increase with heated oxygen is usually less than 1°C per hour.

Lavage by gastric or esophageal balloons also produces a slow temperature increase and has been shown to be effective [156]; however, this method involves risk of aspiration and ventricular fibrillation during balloon insertion. Peritoneal lavage safely raises temperatures at a rate of up to 4°C per hour [80,94,157–159]. Average warming rates, however, are closer to 2°C per hour. Saline or dialysate fluid is heated to 38°C to 43°C and exchanged every 15 to 20 minutes. Alternatively, two peritoneal trocars can be placed and a continuous infusion and drainage circuit can
be established. Pleural lavage with two chest tubes also appears to be effective [160,161].

Insertion of femoral artery and vein catheters allows blood to be removed, heated, and returned to the body. This is usually performed with a hemodialysis machine [144] or pump oxygenator that used during cardiopulmonary bypass. Rewarming at a rate of 1°C to 2°C per hour has been reported by passing the blood from a surgically created arteriovenous fistula through a countercurrent fluid warmer with [162] or without [163,164] a roller pump. For patients with severe cardiopulmonary collapse, a pump oxygenator offers the advantage of hemodynamic support, rapid elevation of temperature, and nearly complete regulation of acid–base and oxygen disorders [66,74,111,119,142,165,166]. In one review of 68 patients presenting with a mean core temperature of 21°C and being treated with cardiopulmonary bypass primarily by the femoral route, there was a 60% survival, and 80% of survivors returned to their previous level of function [166]. No survival is reported in patients presenting with temperatures of less than 15°C. In cases of profound hypothermia, a median sternotomy approach may be preferable because of the possibilities of direct cardiac massage, improved blood flow, and easy access [111].

The desired rate of rewarming varies according to the patient’s cardiopulmonary status and underlying disease. Results of experiments performed on hypothermic dogs suggest that if intramyocardial temperature gradients can be maintained at less than 2°C, the risk of fibrillation decreases [72]. This research argues that safe warming should be either slow enough to allow uniformity in tissue temperatures or fast enough to minimize the period of risk. Slower warming techniques allow a prolonged period of hypothermia and presumably should produce a higher risk of infection because of prolonged immune suppression and a higher incidence of acid–base and intravascular volume problems. A diagnosis of diabetes or myxedema may also influence the desired rate of rewarming. For diabetic ketoacidosis, for example, insulin resistance and the severity of the acidosis could be substantially improved by rapid rewarming [95].

The rewarming method selected must be appropriate for the individual patient being warmed. In one study of 55 patients with accidental hypothermia, extracorporeal membrane oxygenation was used for those in cardiopulmonary arrest; peritoneal dialysis for those with unstable hemodynamics; and airway rewarming, insulation, and warmed fluids for those with stable hemodynamics. Survival was 100% [167].
IATROGENIC HYPOTHERMIA

Iatrogenic hypothermia occurs frequently in surgical recovery rooms and intensive care units [168–171], is associated with increased morbidity, and can be minimized with a systematic team approach. Although subnormal temperatures occur frequently during the postoperative period, frank hypothermia (temperature <35°C) is uncommon. In a series of 195 patients who underwent noncardiothoracic surgery, 60% had temperatures less than 36°C, 29% had less than 35.5°C, and 13% had less than 35°C [172]. Iatrogenic hypothermia results from the infusion of blood products or fluids at lower than body core temperatures [168,172], from continuous ultrafiltration at high flow rates in the intensive care unit [173], and from anesthesia and surgery performed in cool (<23°C) operating rooms [21,22,69,174,175]. In another series of 101 patients undergoing elective surgery under general anesthesia, 78% had temperatures less than 36°C. The average temperature decrease was 0.77°C, and maximal decrease was 2.5°C [175].

Causes and Pathogenesis

Perioperative hypothermia results from increased heat loss, decreased heat production, and compromised thermoregulation [176]. Heat loss may be increased by loss of behavioral control mechanisms, decreased insulation because of exposure of larger skin surfaces, cutaneous vasodilation resulting from anesthetics, increased evaporative losses from serosal surfaces and volatile antiseptics applied to skin, and exposure to air-conditioned environments. Decreased heat production results from muscular paralysis. Impaired thermoregulation results from slowed or compromised afferent and efferent nerve impulses and hypothermic reflexes because of sedative anesthetics. Redistribution of heat from the core to the periphery is felt to be a primary factor for perioperative hypothermia. Temperature change may be abrupt with a 1°C core heat loss within 30 minutes of induction because of redistribution of heat from the core to the periphery [177].

The frequency and severity of heat loss increases with patient age [168,170,171], open chest or abdominal surgery [168,170,178], low-operating room temperature [21,22], length of surgery [169], infusion of cool IV solutions, and certain types of anesthetics. Elderly patients experience a decrease in temperature, shiver less frequently, and take longer to rewarm than do younger patients [168,171]. Temperature decrease during surgery involving open body cavities may result in almost twice the decrease in temperature seen in extremity surgery [170].
Lightly anesthetized, paralyzed, draped patients who are not provided with active warming experience a temperature decrease of 0.3°C per hour at ambient temperatures less than 21°C [22]. Surgery involving muscle paralysis with curare-type agents produces twice the temperature decrease in nonparalyzing procedures [170]. Although halothane and epidural anesthesia may increase heat loss because of vasodilation, no major differences have been detected in the heat loss from most inhalational agents [170,171]. Laparoscopic procedures produce hypothermia that may be more severe than open laparotomy. Massive infusion of chilled solutions can induce hypothermia, as heat loss from infusion of room temperature solutions approximates 16 kcal per L [171]. Blood infused at its stored temperature of 4°C produces a heat loss of 32 kcal per L [172]. In an average human, infusion of 1 L of 4°C blood produces a 0.5°C decrease in temperature [168]. The mean temperature of patients given more than 20 units of blood in 24 hours has been reported to be 32.9°C ± 1.7°C [53]. The rapid transfusion of blood not warmed to body temperature must be considered a risk factor for the development of mild hypothermia. There was no difference in mean temperature of survivors and nonsurvivors after massive transfusion.

Pathophysiology

Perioperative complications from mild hypothermia arise directly from the hypothermia and from the hypermetabolism triggered by the patient’s efforts to restore body temperature. An otherwise healthy individual with a temperature ranging from 34°C to 36°C will have (a) a slightly increased cardiac output, (b) an oxygen consumption up to five times basal levels, (c) an elevated SVR because of peripheral vasoconstriction, (d) a decrease in mixed venous oxygen saturation because of increased oxygen extraction, (e) shivering or muscle rigidity, and (f) a slightly depressed mental status. The alveolar–arterial oxygen gradient and even the arteriovenous oxygen difference [76] may be in the normal range [124]. Therefore, deviations from this pattern during the perioperative period and subsequent morbidity must reflect the additive effects of surgery and anesthesia on metabolism.

For critically ill postoperative patients with cardiac depression, one must be concerned about the potential effects of mild hypothermia because an increase in oxygen consumption could lead to acidosis and hypoxemia. Although acidosis results from an increase in anaerobic metabolism as metabolic demand outstrips oxygen delivery, minute ventilation is usually maintained to the degree necessary to preserve
acid–base balance [179]. Hypoxemia may result from the combination of increased pulmonary parenchymal shunt (venous admixture) after surgery and lower mixed venous PO$_2$. In one study, shivering appeared to be accompanied by a drop in PaO$_2$; arterial oxygen saturation fell below 90% in 53% of shivering patients and remained above 90% in all nonshivering patients [179]. Decreased temperature and shivering can elevate oxygen consumption and, in some patients, lower PaO$_2$ [171,180]. Increased perioperative cardiac ischemia, ventricular tachycardia [181], delayed wound healing [106], perioperative bleeding requiring transfusion [107,182,183], increased length of stay in recovery, and increased length of stay in hospital [106] may occur with perioperative hypothermia. Patients with prolonged postoperative hypothermia have a higher mortality than those who return to normal temperatures in the first postoperative hour [184].

Prevention and Treatment

Numerous interventions have been attempted to minimize perioperative temperature decrease and shivering. The use of postoperative warming blankets alone does not prevent significant temperature loss because the body surface area exposed to heat is small [18,174,185]. The use of warming blankets along with heating of all infused liquids can maintain average temperature on arrival in the recovery room above 36°C [185]. Heating and humidifying the carbon dioxide used for laparoscopic insufflation to 30.0°C to 30.5°C decrease the heat loss associated with laparoscopic procedures [186]. Crystalloids can be easily warmed in a microwave oven to 39°C in 2 minutes [187]. The inhalation of heated, humidified air can be safely applied to most intubated patients and is effective for preventing temperature loss [180,188,189] and shivering [180]. Most publications clearly favor the use of preoperative, intraoperative, and postoperative forced air warmers [190–192]. One hour of prewarming with an air warmer set to 43°C may minimize redistribution loss and decrease hypothermia for brief procedures. Vasodilators such as nitroprusside or nifedipine may be started hours preoperatively, resulting in peripheral vasodilation and minimizing redistribution loss by prewarming the peripheral tissues. Cutaneous rewarming minimizes shivering. Meperidine may lower the shivering threshold and control pain in postoperative patients. Prewarming is felt to be the most effective strategy for high-risk patients [177].

Prevention of the development of hypothermia in summary includes minimizing preoperative and postoperative time in chilled rooms, covering the patient with drapes or blankets whenever possible, and infusing all solutions at least at room temperature. High-risk patients including those undergoing major abdominal or cardiothoracic surgery,
surgery involving intentional hypothermia, or surgery with anesthesia times in excess of 4 hours; patients older than 60 years undergoing surgery; or those with known or expected cardiac depression should receive preventive measures, including preoperative [193–195] and intraoperative [191,196] forced warm air, heating of infused solutions to 37.5°C, and inhalation of heated humidified oxygen. In any patient undergoing extracorporeal bypass, a heat exchanger to the bypass circuit should be used [197]. Blood and colloid solutions should be heated to 37.5°C [198].
INTENTIONAL HYPOTHERMIA

Intentional hypothermia has been induced by partial immersion or surface or central cooling techniques to treat cancer, limit the toxicity of sepsis, help prevent the alopecia of chemotherapy, reduce carbon dioxide production in refractory status asthmaticus, assist in the amputation of limbs, and minimize the hypoperfusion injury associated with cardiothoracic surgery. Currently, mild-to-moderate hypothermia (32°C to 36°C) is the first treatment with proven efficacy for postischemic neurologic injury, and employing intentional hypothermia to retard postcardiac arrest brain injury is now recommended by the American Heart Association [226,220].

Therapeutic Hypothermia After Cardiac Arrest

Therapeutic hypothermia improves survival and neurologic outcomes after sudden cardiac arrest, and has been summarized in a systematic review and meta-analysis of six randomized trials including 1,413 patients [199–201,225]. According to this review, patients treated with therapeutic hypothermia were more likely to survive than patients whose temperature was not managed similarly (relative risk: 1.41; 95% confidence interval [CI]: 1.09 to 1.82); however, no difference for outcomes was found based on the target temperature of 33°C versus 36°C. Conclusion about the absence of any difference of outcomes based on the target temperature is based primarily on the findings of a large, well-performed, multinational randomized trial of 939 unconscious survivors of out-of-hospital cardiac arrest that reported no differences of mortality or neurologic function between patient’s treated with a target temperature of 33°C (n = 473) compared to patients with a targeted temperature of 36°C (n = 466) [220].

Cardiac arrest results in immediate termination of blood flow and loss of oxygen, leading to neurologic ischemic injury after only several minutes and permanent loss after 5 to 10 minutes. If resuscitation results in restoration of circulation, then an additional reperfusion injury occurs. Several animal models, including dogs, showed that cooling after prolonged cardiac arrest provided considerable neurologic benefits [203]. Subsequently, two pivotal, randomized, controlled trials were conducted and confirmed efficacy [200,201]. The first of these was a large, multicenter, randomized controlled trial that enrolled 275 patients in 9 European hospitals who had sustained a cardiac arrest with an initial rhythm of ventricular fibrillation. The second randomized controlled trial enrolled 77 patients from 4 hospitals in Victoria, Australia, with similar
inclusion criteria, however, did not exclude older patients or those who were hypoxic. The American Heart Association recommended, in review of these two studies, therapeutic hypothermia for 12 to 24 hours following resuscitation from out-of-hospital cardiac arrest for the treatment of neurologic injury when the initial rhythm is ventricular fibrillation [204].

Therapeutic hypothermia is of potential benefit for minimizing brain injury in all postcardiac arrest patients, regardless of their arrhythmia or the location of their arrest according to the 2010 Guidelines for Advanced Cardiac Life Support [226]. Nonetheless, evidentiary support for therapeutic hypothermia in nonshockable rhythms is primarily limited to nonrandomized studies using historic or concurrent controls [205]. One subgroup analysis of 186 patients with a nonshockable rhythm reported no difference in mortality between those treated with temperature management using a target of 33°C versus a target of 36°C [220].

In addition, the trials used therapeutic hypothermia several hours after resuscitation; therefore, the role for earlier cooling or prolonged cooling was not evaluated. In a Cochrane database systematic review, when combined with standard postcardiac arrest care, lowering the body temperature to the range of 32°C to 34°C during the first hours after cardiac arrest improves neurologic outcomes compared to not controlling body temperature [219]. A large randomized trial reports similar improvements in outcome whether the temperature is maintained at 33°C or 36°C [220]. Given that the induction of hypothermia has become more feasible, the side effects are generally easily managed in the critical care setting, and there is a benefit for anoxic brain injury; consideration may be given to treat comatose postcardiac arrest nonventricular fibrillation patients with therapeutic hypothermia [205].

Hyperthermia must be avoided following cardiac arrest. Failure to control a patient’s core temperature is associated with the development of fever and worse neurologic outcomes [221,222]. According to an observational study of 151 patients, the risk of death increases for each degree over 37°C during the first 48 hours after cardiac arrest (odds ratio: 2.26; 95% CI: 1.24 to 4.12) [221]. Earlier onset of fever is associated with worse outcomes, whereas delayed fever onset has not shown the same deleterious effects [222]. Overall, these data suggest that active control of the postcardiac arrest patient’s core temperature, with a target between 32°C and 36°C, followed by active avoidance of fever, is the optimal strategy to promote patient’s survival.

For Acute Myocardial Infarction
Timely myocardial reperfusion using thrombolytic therapy or angioplasty is the most effective therapy for patients with ST elevation myocardial infarction. Although mild hypothermia appears feasible and safe, its ability to limit infarct size or reduce rates of adverse cardiac events has not been proven [206].

For Spinal Cord Injury
Hypothermia strategies date back to the 1960s for the treatment of acute spinal cord injury, but no randomized phase III trials have been conducted to confirm efficacy and safety, let alone the appropriate therapeutic window. Hypothermia remains an experimental treatment with unknown clinical relevance for patients with acute spinal cord injury [207].

For Ischemic and Hemorrhagic Stroke
Hypothermia reduces brain edema and intracranial pressure (ICP) in patients with traumatic brain injury; however, only very few small pilot studies have investigated the role hypothermia may have in the treatment of acute ischemic stroke. There are no controlled trials performed for hypothermia in hemorrhagic stroke [208]. The use of normothermia protocols is being actively studied.

For Acute Liver Toxicity
Patients with rapidly progressive acute liver failure, such as with acetaminophen overdose, are at high risk for developing cerebral edema, intracranial hypertension, brainstem herniation, brain death or anoxic brain injury, and permanent brain impairment. Techniques such as manipulating the body position, increasing sedation, and increasing osmolarity through medications can temporarily control this phenomenon. However, these steps often postpone but do not stop the development of brain herniation unless liver transplantation or spontaneous liver regeneration follows immediately. Using therapeutic hypothermia has been shown to effectively bridge patients to transplant by reducing cerebral edema and intracranial hypertension by decreasing splanchnic ammonia production, lowering oxidative metabolism within the brain, and restoring normal regulation of cerebral hemodynamics [209]. However, hypothermia has not been adequately studied for its safety, and concerns of increasing the risk of infection, cardiac arrhythmias, and bleeding may be accentuated. Multicenter, randomized control trials are needed to determine whether hypothermia protects the brain and improves survival without causing harm.
In Multisystem Trauma

Hypothermia may be helpful in attenuating the damage to tissues before adequate blood volume resuscitation can be restored in traumatic blood loss. Clinical trials to determine its efficacy are needed [210]. Advances in hypothermia, based on randomized controlled trials or meta-analyses of such trials, are summarized in Table 184.4.

**TABLE 184.4 Advances in Management of Hypothermia Based on Randomized Controlled Trials**

Induced hypothermia benefits survivors of cardiac arrest:
Unconscious adult patients with recovery of spontaneous circulation after out-of-hospital cardiac arrest should be cooled with a target between 32°C and 36°C for 12–24 h when the initial rhythm was VF, followed by active avoidance of fever for at least 48 h following cardiac arrest. Similar therapy may be beneficial for patients with non-VF arrest out-of-hospital or for in-hospital arrest.

VF, ventricular fibrillation.

**Methods of Cooling**

Induction and maintenance of hypothermia requires blocking the body’s normal thermoregulation mechanism as well as active heat exchange. Therapeutic hypothermia can be achieved through four mechanisms individually or in combination, which include conduction, convection, radiation, and evaporation as previously described. There are four phases of temperature modulation during therapeutic hypothermia: induction, maintenance, rewarming, and normothermia [211]. Induction is typically initiated prehospital, especially in out-of-hospital cardiac arrests, but can occur in hospital for patients awaiting a liver transplantation, with cerebral edema from acute liver failure and for control of refractory elevated ICP. In cardiac arrest survivors, contraindications to perform therapeutic hypothermia would include if the patient can follow verbal commands, more than 8 hours have elapsed since return of spontaneous circulation, life-threatening bleeding or infection, cardiopulmonary
collapse is imminent despite vasopressor or mechanical hemodynamic support, or an underlying terminal condition exists.

Induction is commonly achieved by rapid bolus administration of 30 to 40 mL per kg cold (4°C) isotonic resuscitation fluid [211] targeting a goal temperature of 32°C to 36°C. Serum potassium will drop, and empirically repleting potassium for a goal of more than 3.8 mEq per dL is needed. Close monitoring and treatment for seizures are necessary. Simultaneous sedation, paralysis (for shivering), and use of commercial surface or intravascular cooling devices are concomitant therapeutic strategies [211].

Maintenance phase occurs in the intensive care unit and is a phase where both metabolic and hemodynamic homeostasis are maintained. The core temperature is kept at 33°C for 18 to 24 hours. Maintenance of brain perfusion by keeping mean arterial perfusion pressure at 65 mm Hg or more (cerebral perfusion pressure [CPP] may need to be monitored given cerebral autoregulatory failure [212]), normocarbia with volume-cycled mechanical ventilation to maintain a normal pH as hypercarbia is to be avoided; maintain a perfusing rhythm, antibiotic prophylaxis if pulmonary infiltrates present [211,213], maintenance of a blood glucose of 120 to 160 mg per dL [212], maintenance of normal electrolyte levels and appropriate medication dosing given the reduction in drug metabolism and duration of action, skin care, and aggressive treatment of shivering with neuromuscular blockade [211].

After 24 hours of therapeutic hypothermia, the gradual rewarming phase starts and is associated with hemodynamic instability often referred to as the postresuscitation syndrome. It is characterized by an increase in inflammatory cytokine levels, vasodilatation, and hypotension. The patient is also at increased risk for an elevation in the ICP and a decrease in the CPP. Gradual rewarming at a goal rate of 0.2°C to 0.33°C per hour until the patient is at 36.5°C or 37°C is preferred to avoid large hemodynamic fluctuations. Supportive fluid boluses, inotropes, and vasopressors may be necessary to maintain CPP, especially if there are signs of elevated ICP. The use of neuromuscular blockade until the temperature reaches 35°C to avoid shivering and sedation is weaned once the body temperature reaches 36°C is recommended [211].

For patients who have undergone therapeutic hypothermia postcardiac arrest, a rebound fever can occur and is harmful [214,221,222]. Brain injury may be attenuated by fever control [215]. Maintaining normothermia for at least 72 hours from return of circulation is thus common practice [211]. This is easily achieved by employing commercial
cooling devices and resetting target temperature to 36.5°C to 37.5°C. Nursing attention to onset of fever spikes and frequent adjustments to the cooling device set points need to be closely observed.

A number of issues occur with induction, maintenance, and withdrawal of therapeutic hypothermia and require close attention. (i) Serum potassium needs to be aggressively replaced if levels are less than 3.8 mEq per dL as soon as therapeutic hypothermia is employed and the levels should be followed every 3 to 4 hours during the induction phase. (ii) Accurately measure the core temperature continuously, preferably achieved by esophageal measurements. (iii) With neuromuscular blockade, a thorough neurologic examination and adequate sedation a priori are important. (iv) There is no evidence demonstrating the superiority of any cooling method, and, in clinical practice, a combination of intravascular and surface cooling is commonly employed. (v) The incidence of pneumonia in postcardiac arrest patients treated with hypothermia is 30% to 50% [201]. The etiology may be related to aspiration at the time of cardiac arrest or from the immunosuppressive effects from hypothermia. Preliminary data support therapeutic antibiotics for presumed pneumonia with de-escalation based on culture results [213]. (vi) Seizures can occur 19% to 34% of the time and go undetected with neuromuscular blockade [216]. Thus, continuous electroencephalography monitoring of the paralyzed patient may be necessary. If continuous monitoring is not available, then empirically using antiepileptic drugs with sedative effects to sedate the patient may be warranted [211]. (vii) Hemodynamic instability is common during the rewarming phase because of cutaneous vasodilatation and the inflammatory state [211]. Close attention to monitoring adequate cardiac output, global tissue perfusion, and brain perfusion using IV isotonic fluids, inotropes, and/or vasopressor agents may be necessary. Hemodynamic monitoring may be achieved using invasive or noninvasive cardiac output devices, urinary output if kidney function is normal, and central venous oxyhemoglobin saturation for tissue perfusion or direct invasive monitoring of brain metabolism [211]. (viii) To reduce shivering, focal counter rewarming [211] can be employed in which the face, neck, and extremities are actively warmed, whereas the torso and central venous system are cooled. This paradoxically increases the cooling process by enhancing the cutaneous vasodilatation.
COOLING TECHNIQUES

The conventional method involves the infusion of cold saline or ringer’s lactate solution at 4°C administered at 30 to 40 mL per kg through a peripheral vein and has been shown to decrease core temperature by 2°C to 4°C without left ventricular systolic dysfunction and a reduction in cardiac output [217]. This method is supported by multiple safety and efficacy trials [211] and should be the preferred method for induction in conventional cooling. Thereafter, cooling can be maintained with ice packs applied to the neck, groin, and axilla and rubber cooling mats or blankets as used in the operating room. Ongoing infusion of cold fluid has not been shown to be an effective method to maintain hypothermia [218]. A number of issues associated with this method include the lack of an internal feedback loop making accurate temperature maintenance difficult, a high incidence of overcooling, and the need for a high level of nursing care. Nonetheless, it is widely available and cost-effective.

Patients with a history of heart failure or severely compromised renal function, or signs of acute pulmonary edema, should not receive rapid cooled infusions to induce therapeutic hypothermia. Surface cooling measures or an IV cooling device should be used instead. There is no evidence demonstrating the superiority of any cooling method, and, in clinical practice, a combination of intravascular and surface cooling is commonly employed. The lone observation study comparing intravascular and surface cooling methods found that neither the time needed to reach the goal temperature nor neurologic outcomes were significantly different between the two groups [223]. The effect of mild temperature fluctuations and excessive hypothermia on patient outcomes is unknown, and thermostatically controlled devices provide the most precise minute-to-minute temperature regulation and can avoid fever [224].

Chapter 185
Disorders of Temperature Control, Part II: Hyperthermia
MARY KATHRYN STEINER • RICHARD S. IRWIN

This chapter reviews the pathobiology, pathophysiology, diagnosis, differential diagnosis, and treatment of four major hyperthermic syndromes—heat stroke, malignant hyperthermia (MH), neuroleptic malignant syndrome, and drug-induced hyperthermia (DIH).

HEAT STROKE

Heat stroke is defined as a core body temperature usually in excess of 40°C (104°F) characterized by central nervous system (CNS) dysfunction in the setting of a large environmental heat load that cannot be dissipated.

Causes and Pathogenesis
There are two types of heat stroke: exertional and nonexertional (classic, heat stroke). Exertional heat stroke is seen in younger individuals, otherwise healthy, exercising at higher than normal ambient temperatures and humidity. Typical patients are athletes and military recruits in basic training. The thermoregulatory mechanisms are intact, but overwhelmed by the thermal challenge of the environment and the increase in endogenous heat production. Nonexertional heat stroke occurs in individuals >70 years with underlying chronic medical conditions during a heat wave. Patients frequently have some impairment of thermoregulatory control, and temperatures rise easily with increased thermal challenge.

The causes of heat stroke fall into two categories (Table 185.1): increased heat production and impaired heat loss.

| TABLE 185.1 Causes of Heat Stroke |
Increased heat production
  Exercise
  Fever
  Thyrotoxicosis
  Amphetamines
  Hallucinogens

Impaired heat loss
  High ambient temperature or humidity
  Ineffective voluntary control
  Lack of acclimatization
  Dehydration
  Cardiovascular disease
  Hypokalemia

Drugs
  Anticholinergics
  Phenothiazines
  Butyrophenones
  Thiothixenes
  Barbiturates
  Anti-Parkinson’s agents
  Diuretics
  β-Blockers
  Alcohol

Debilitating conditions
  Skin diseases
  Cystic fibrosis
  Central nervous system lesions
  Older age

Increased Heat Production

Endogenous heat production during exertion ranges from 300 to 900 kcal per hour. Even in conditions favoring the maximal evaporation of sweat, only 500 to 600 kcal per hour of heat may be lost. Endogenous heat production may also be increased by fever, thyrotoxicosis, or the hyperactivity associated with amphetamine and hallucinogen use. In these conditions of increased thermogenesis, especially during maximal exercise, a healthy individual with intact regulatory mechanisms may
develop hyperthermia.

**Impaired Heat Loss**

Schizophrenic, comatose, senile, or mentally deficient patients are at increased risk of heat stroke when ambient temperatures are high, owing to impaired voluntary control [5,6]. These patients may fail to perceive a temperature rise and to take appropriate action. Impermeable clothing in hot environments prevents evaporative heat loss, and individuals may suffer heat stroke [7,8].

Acclimatization increases heat tolerance by increasing cardiac output, decreasing peak heart rate, and increasing stroke volume. This lowers the threshold necessary to induce sweating, increases the volume of sweating, and, via an increase in aldosterone, expands extracellular volume and minimizes sodium loss in sweat [9,10]. However, unacclimatized individuals who do not mount an adaptive response are at increased risk of suffering exertional heat stroke [11].

Dehydration and impaired cardiovascular performance increases the risk of heat stroke owing to a decrease in skin or muscle blood flow, thus decreasing the movement of heat from the core to the environment [10,12]. Hypokalemia increases the risk of heat stroke by decreasing muscle blood flow, impairing cardiovascular performance, and decreasing sweat gland function [9,10]. Adequate fluid intake and maintenance of a normal vascular volume prevents heat stroke.

Many drugs are known to predispose to heat stroke. Anticholinergic drugs such as phenothiazines, butyrophenones, thiothixenes, and anti-Parkinson’s medications reduce sweat activity [14]. Barbiturate overdose may produce sweat gland necrosis [10]. Diuretics promote dehydration and hypokalemia. β-Blockers may increase the risk of heat stroke by cardiac depression. Alcohol consumption may increase the risk of heat stroke 15-fold because of dehydration secondary to antidiuretic hormone inhibition and inappropriate vasodilation [6].

Skin disorders that impair sweat gland function, such as cystic fibrosis and chronic idiopathic anhydrosis, predispose to heat stroke [15].

Hypothalamic lesions impair thermoregulation. During the early stages of heat stroke, the hypothalamus regulates autonomic responses to limit hyperthermia. In the later stages, once thermal toxicity occurred, hypothalamic regulation is impaired [16]. Anhydrosis has been reported in up to 100% of heat stroke victims in some series [17]. The hypothalamic set point may be elevated. The exact cause of hypohidrosis remains unclear and may reflect hypothalamic dysfunction or the secondary effects of dehydration and cardiovascular collapse. Electron microscopic studies of eccrine sweat glands in a patient with fatal exertional heat stroke show changes suggestive of sweat gland fatigue.
Heat stroke can, however, occur among individuals who perspire profusely, indicating that sweat gland malfunction is not the only factor contributing to the pathogenesis of the syndrome.

The increased risk of heat stroke among the elderly is predominantly owing to a decreased ability to sweat and a compromised cardiovascular response to heat exposure when compared with younger individuals [8,19]. In one report, 84% of elderly patients showed no evidence of sweating at the time heat stroke was diagnosed [20]. Elderly patients are more likely to have deficient voluntary control, poor acclimatization, and they take drugs that adversely affect thermoregulation.

Pathophysiology

The primary injury of heat stroke is caused by direct cellular toxicity of temperatures above 42°C, the critical thermal maximum [21]. Cell function deteriorates owing to cessation of mitochondrial activity, alterations in chemical bonds involved in enzymatic reactions, and cell membrane instability. This toxic effect may account for the widespread organ damage seen in all three of the major hyperthermic syndromes [22].

Heat stress activates numerous cytokines that modulate the body’s response to increased temperature [23]. For most cases, the inflammatory response of heat stroke parallels that seen for heat stress from exertion. Tumor necrosis factor α, interleukin (IL)-1β, IL-2, IL-6, IL-8, IL-10, IL-12, and interferon γ are typically increased with heat stroke. IL-6 is activated in the muscles and modulates inflammatory response by controlling cytokine levels and hepatic production of acute phase proteins. Endotoxemia from bacterial translocation of an ischemic gut further exacerbates the inflammatory response. Endothelial injury activates the coagulation cascade, promoting a prothrombotic state. Heat shock proteins are transcribed in response to heat stress and act on the brain to induce tolerance to heat stress [24].

Dehydration, metabolic acidosis, and local hypoxia alter the pathophysiologic consequences and clinical presentation of each of the hyperthermic syndromes. For example, classic heat stroke may occur with relatively little metabolic acidosis because no exertion was involved in its onset; however, it may be associated with more pronounced dehydration caused by the gradual rise in temperature and prolonged sweating. Exertional heat stroke, alternatively, may be accompanied by a severe metabolic acidosis and hypoxia caused by muscular exercise. It is
typically associated with a more normal volume status because the onset of temperature elevation is abrupt.

**Muscle Effects**

Muscle degeneration and necrosis occur as a direct result of high temperatures. Muscle damage is more severe with exertional heat stroke owing to local increases of heat, hypoxia, and metabolic acidosis associated with exertion. Significant muscle enzyme elevation and severe rhabdomyolysis are extremely common among exertional heat stroke victims \[12,25,26\] but rare with classic heat stroke \[27\].

**Cardiac Effects**

Cardiac output is increased \[28\] owing to increased demands and low peripheral vascular resistance secondary to vasodilation and dehydration. Dehydration frequently results from sweat rates that may easily reach 1.5 to 2.0 L per hour during episodes of heat stroke \[29\]. Central venous pressure is initially elevated \[30\]. Hypotension occurs commonly as a result of high-output failure or temperature-induced myocardial hemorrhage and necrosis with subsequent cardiac depression and failure \[9,12,31\]. Tachyarrhythmias are frequent. Postmortem specimens show focal myocytolysis, myocyte necrosis, and hemorrhage in subepicardial, intramuscular, subendocardial, or intravalvular tissues \[32\].

**Central Nervous System Effects**

Direct thermal toxicity to brain and spinal cord rapidly produces cell death, cerebral edema, and local hemorrhage. These may lead to profound stupor or coma, almost universal features of all the hyperthermic syndromes. Seizures secondary to edema and hemorrhage are not uncommon. Because Purkinje cells of the cerebellum are particularly sensitive to the toxic effects of high temperatures, ataxia, dysmetria, and dysarthria may be seen acutely and in survivors of hyperthermia \[10,33\]. Progressive cerebellar atrophy has been documented by computed tomography (CT) and magnetic resonance imaging (MRI) \[34\]. Lumbar puncture from those with classic and exertional heat stroke may reveal increased protein levels, xanthochromia, and a slight lymphocytic pleocytosis \[12,20\]. Survivors of severe heat stroke may show premature cataract formation, considered to be secondary to dehydration \[35\]. Up to 33% of survivors of heat stroke have at least moderate neurologic impairment after discharge from the hospital \[36\].
Renal Effects

Renal damage occurs in nearly all hyperthermia patients; it is potentiated by dehydration, cardiovascular collapse, and rhabdomyolysis. In classic heat stroke, acute renal failure occurs on average in 5% of patients as a result of dehydration [9]. In exertional heat stroke, acute renal failure occurs in up to 35% of cases [9,31]. Dehydration, pigment load, hypoperfusion, and urate nephropathy are thought to contribute to a clinical picture of acute tubular necrosis [31]. Other features include low serum osmolarity, moderate proteinuria, active sediment, and characteristic machine-oil appearance of the urine. In one series, the incidence of acute tubular necrosis increased with survival time [32]. Hypocalcemia and creatinine phosphokinase values above 10,000 U per L increase the risk of acute renal failure [37]. Respiratory alkalosis is common for mild hyperthermia, with metabolic acidosis predominating at temperatures greater than 41°C [24].

Gastrointestinal Tract Effects

The combination of direct thermotoxicity and relative hypoperfusion of the intestines during hyperthermia leads to ischemic intestinal ulcerations that may result in frank bleeding [9]. Hepatic necrosis and cholestasis occurs 2 to 3 days after hyperthermic insult, and 5% to 10% of the cases result in death [10].

Hematologic Effects

White blood cell counts are elevated owing to catecholamine release and hemoconcentration. Anemia and a bleeding diathesis [29] are present owing to (a) direct compromise of platelets and bleeding factor functions by heat, (b) a decrease in coagulation factor synthesis from liver failure, (c) a decrease in platelet and megakaryocyte counts, (d) platelet aggregation [38], and (e) disseminated intravascular coagulation (DIC). Megakaryocyte counts are reduced in up to 50% of specimens, and surviving megakaryocytes are morphologically abnormal [32]. DIC is present among most cases of fatal hyperthermia [32,39], most frequently appearing on days 2 and 3 after hyperthermic insult. It is considered to be caused by activation of the clotting cascade by vascular endothelial damage and generalized cell necrosis [40]. Among cases of DIC, cardiac, CNS, pulmonary, gastrointestinal (GI) tract, and renal complications are more frequent and severe. An increase in blood viscosity up to 24% has been postulated to facilitate thromboses [41].
Endocrine Effects

Hypoglycemia may occur among severe exertional heat stroke victims caused by metabolic exhaustion [26]. Among milder heat stroke patients, hyperglycemia and elevations of serum cortisol have been reported [42]. Although at autopsies the adrenal glands frequently show pericortical hemorrhages, survivors show little evidence of adrenal dysfunction [22,31]. Growth hormone and aldosterone levels actually increase abruptly during severe, acute heat exposure and are thought to act to preserve volume.

Electrolyte Effects

Hyperthermia produces frequent imbalances in potassium, sodium, phosphate, and calcium levels [29,43]. Among heat stroke victims, sweating involves the active excretion of potassium from the body, producing normal to low serum potassium levels and decreased total body potassium concentrations. Among cases of exertional heat stroke with severe cell injury, potassium levels may be extremely elevated because of cell lysis. Although mild hypophosphatemia occurs frequently as a result of intracellular trapping and parathyroid hormone resistance, phosphate levels may decrease to less than 1 mg per 100 mL in cases of hyperthermia with severe rhabdomyolysis [43]. Calcium values may fall 2 to 3 days after cellular injury owing to intracellular precipitation. Among patients with severe tissue injury, rebound hypercalcemia may occur 2 to 3 weeks after hyperthermia as a result of parathyroid hormone activation [43].

Pulmonary Effects

Direct thermal injury to the pulmonary vascular endothelium may lead to cor pulmonale or acute respiratory distress syndrome. This and the tendency toward myocardial dysfunction make pulmonary edema common. Increased oxygen demands and acidosis frequently produce a respiratory alkalosis. Metabolic acidosis is, however, the most common acid–base disorder [44].

Diagnosis

The diagnosis of classic heat stroke is made clinically based on an elevated rectal temperature above 40°C (>104°F), CNS dysfunction, and exposure to severe environmental heat.
Heat stroke should be expected for any patient exercising in hot weather or in susceptible individuals during heat waves (see Table 185.1). Coma or profound stupor is nearly always present, but other traditional criteria of anhidrosis and core temperature above 41°C may be absent. Although anhidrosis occurs in 84% of elderly patients with classic heat stroke [20], profuse sweating is typically present in exertional heat stroke [10]. Thus, the presence of anhidrosis is helpful, but its absence is not. Likewise, by the time the patient receives medical care, the temperature may have fallen significantly owing to cessation of exertion, removal from a hot environment, or cooling measures undertaken during transport. Most patients do have a temperature above 40°C, however. Other examination findings include vital sign abnormalities (e.g., tachycardia, tachypnea, and hypotension), flushing, pulmonary crackles, and oliguria.

Risk Factors for Increased Mortality

Patients who present to the hospital with heat stroke have high mortality, with rates ranging from 21% to 63% [241]. Mortality correlates with the degree of temperature elevation, time to initiation of cooling measures, and the number of organ systems affected [242]. According to one prospective cohort study, the risk of death increases for patients who present with anuria, coma, or cardiovascular failure [243]. Patients who take antihypertensives, lack air conditioning, are socially isolated, or are unable to take care of themselves are also at high risk [17, 20–22].

Diagnostic Evaluation

Serial rectal temperatures (accurate at high temperatures) should be obtained for all patients with heat stroke to assess and monitor. A chest radiograph may show pulmonary edema. The electrocardiogram may show dysrhythmias, conduction disturbances, nonspecific ST-T changes, or heat-related myocardial ischemia or infarction [244,245]. Laboratory studies may reveal coagulopathy, acute kidney injury, acute hepatic necrosis, and a leucocytosis as high as 40,000 per mm³ [246]. Arterial blood gas may reveal metabolic acidosis and respiratory alkalosis. Serum creatinine kinase and urine myoglobin help detect rhabdomyolysis and its complications (e.g., hypocalcemia, hyperphosphatemia, elevated BUN and creatinine). Toxicology screening, a head CT, and analysis of the cerebrospinal fluid (CSF) may be helpful when altered mental status is present.

Differential Diagnosis

The differential diagnosis of severe hyperthermia includes infectious,
endocrine, CNS, toxic, and oncologic causes [54]. Table 185.2 lists the common causes of hyperthermia. Classic heat stroke is often distinguished from other conditions by history and examination. However, the clinical picture can be unclear. No single diagnostic test definitively confirms or excludes heat stroke, and laboratory abnormalities may overlap in patients with heat stroke and with hyperthermia owing to other causes. For example, patients with heat stroke will meet the criteria for systemic inflammatory response syndrome. In such circumstances, it is prudent to initiate cooling measures while other diagnoses are evaluated. Rapid improvement with active cooling suggests that heat stroke is the main diagnosis but not always. The most important causes of severe hyperthermia owing to failure of thermoregulation are heat stroke, neuroleptic malignant syndrome, and MH.

Treatment

The management of classic heat stroke requires adequate airway protection, breathing and circulation, rapid cooling, and treatment of complications.

Cooling Measures to Decrease Thermogenesis

Evaporative cooling is the method used most often because it is effective, noninvasive, easily done, and allows for other medical care to occur. It is associated with decreased morbidity and mortality in the elderly [247]. Some cooling may be achieved in the field by moving the victim to a shaded cooler area, removing the clothes, constantly wetting the skin, and fanning or transporting in an open vehicle to create a breeze. Once the victim reaches the hospital, cooling and subsequent supportive care are best provided in an intensive care setting.

With evaporative cooling, the naked patient is placed in a cool room and sprayed with a mist of lukewarm water while fans are used to blow air over the moist skin. In one specially designed evaporative cooling unit, patients were sprayed with 15°C water and their skin was fanned at 30 times per minute with air heated to 45°C to 48°C. Temperature reduction was rapid and mortality was 11% [57]. There was no mortality in 25 patients with nonexertional heat stroke treated with cooling by covering with a cool, wet, 20°C sheet and fanning with two 35-cm electric fans. Fanning was adjusted to maintain skin temperature at 30°C to 32°C; skin temperature fell 1°C every 11 minutes [58]. Among 14 patients with nonexertional heat stroke, there was one death when evaporative/convective cooling was used. The median time to return to temperature less than 39.4°C was 60 minutes.

Direct external cooling (DEC) involves immersing the patient in ice water or packing the patient in ice. Ice water immersion with massage has been effective with few reported complications [59], but it complicates monitoring and intravenous (IV) access. Colder water cools
more rapidly (up to 0.35°C per minute), with one study demonstrating that 2°C water cooled volunteers twice as rapidly as 8°C water [60]. Because cold skin temperatures produce vasoconstriction, however, constant massage may be necessary to allow circulation to carry heat from the core. DEC is highly effective but makes patient monitoring and management extremely inconvenient. Therefore, some authors advocate evaporative cooling as a safer cooling method in patients at high risk of cardiovascular collapse [52]. Because comparative studies of cooling techniques use different water temperatures for immersion and different evaporative cooling protocols, there is no consensus on which lowering technique is superior. In most cases, treatment will be determined by what resources are immediately available. The Israeli Defense Forces protocol involves moving the collapsed patient to the shade, removing clothing, splashing the skin with water while fanning, and transporting to the hospital in an open vehicle. These measures yielded a cooling rate of 0.11°C per minute [61]. The US Marine Corps protocol calls for covering the patient with sheets covered with ice and then fanning the patient. This has had no mortalities in 200 cases and has reduced temperatures to below 39°C in 10 to 40 minutes [62].

In rare instances in which evaporative and DEC methods fail to reduce the temperature, peritoneal lavage with iced saline cooled to 20°C or 9°C, gastric lavage, hemodialysis, or cardiopulmonary bypass with external cooling of the blood may be necessary to reduce the temperature. Temperature should be continuously monitored and cooling stopped as it approaches 39°C. Although IV chlorpromazine of 10 to 25 mg has been advocated to prevent shivering during cooling, it is usually unnecessary. Cooling blankets, commonly used, are ineffective and are not recommended [63].

**Pharmacologic Therapy**

It is not required in heat stroke. There is no role for antipyretic agents such as acetaminophen or aspirin because the underlying mechanism does not involve a change in the hypothalamic set—point and they may worsen hepatic injury or DIC. Dantrolene is ineffective in patients with hyperthermia not because of MH [248].

**Complications**

Arrhythmias, metabolic acidosis, and cardiogenic failure complicate the early management of hyperthermic crises. Supraventricular tachyarrhythmias usually require no treatment because they respond to restoration of normal temperature and metabolism. Digitalis should be avoided owing to the likelihood of hyperkalemia.
Hypotension should be treated initially with normal saline and, if necessary, isoproterenol. Dopaminergic and α-agonists should be avoided because they produce peripheral vasoconstriction. Volume expansion with dextran is contraindicated owing to its anticoagulating effect. Pulmonary artery and arterial catheter monitoring may be helpful in the management of hypotension because patients frequently have low peripheral resistance, dehydration, and impaired cardiac function and are at a high risk of congestive heart and renal failure. Because 64% of patients may have a normal central venous pressure before resuscitation, volume expansion in most cases should be guided by intravascular pressure monitoring where available [66]. Seizures, quite common in heat stroke, usually respond to diazepam.

Blood gas status should be determined early in treatment. Blood gases drawn at temperatures above 39°C should be corrected for temperature, although to our knowledge no studies have demonstrated that this is clinically necessary. The solubility of oxygen and carbon dioxide increases as blood drawn from the patient is cooled to 37°C for analysis. This lowers the carbon dioxide and oxygen tensions and elevates the pH when compared with values present in the patient. Therefore, the patient is more acidic and less hypoxemic than the uncorrected values indicate. Normal values of intracellular pH and changes on the body’s buffering system in hyperthermia have been poorly described. Because normal values for blood gases in hyperthermic patients are unavailable, by convention the blood gas values are corrected for temperature, using any reliable nomogram, and clinical decisions are made as if the patient were euthermic [67–69]. The following approximate corrections have been used: for each 1°C that the patient’s temperature is above 37°C, the oxygen tension is increased by 7.2%, carbon dioxide (CO₂) tension increased by 4.4%, and pH is lowered by 0.015 units. More research is needed before definite conclusions can be made. Nevertheless, 100% oxygen should be delivered until adequate oxygenation is ensured. Bicarbonate should be administered, guided by frequently obtained arterial blood gas values. The base deficit is frequently large, and up to 30 g of bicarbonate has been required for correction. Comatose patients should have prophylactic intubation to protect their airways from aspiration.

Urine output should be closely monitored with an indwelling bladder catheter. Patients should be routinely given 1 to 2 mg per kg of mannitol over 15 to 20 minutes to promote continued urine flow and to possibly decrease cerebral edema. Continuous urine output should then be
maintained with intermittent doses of furosemide. In all cases of hyperthermia, serum potassium levels should be closely followed. In cases of oliguria or potential renal failure, polystyrene sulfonate should be given early for hyperkalemia.

Moderate-to-severe liver failure is common, may prolong illness, and, in combination with renal failure, may make administration of several drugs difficult. Histamine receptor type 2 (H₂)–blocking drugs or proton pump inhibitors given prophylactically may decrease the incidence of GI tract bleeding.

Most patients who die of heat stroke have evidence of DIC [70]. Coagulation parameters such as prothrombin time, partial thromboplastin time, platelet count, and fibrinogen should be carefully followed. Should DIC occur, traditional recommendations for treatment should be followed (see Chapter 88).

Steroids are of no known benefit in heat stroke. Infection has not been reported as a major cause of morbidity and mortality in hyperthermia, and antibiotics are associated with superinfections [20,26].

**Prognosis**

Morbidity and mortality are directly related to the peak temperature reached and time spent at elevated temperatures. A delay in treatment of only 2 hours may result in increased mortality up to 70% [11,52]. When heat stroke is swiftly recognized and aggressively treated, mortality should be minimal. For example, in one series of 15 patients with exertional heat stroke, all were successfully treated with no mortality and little morbidity [11]. Another study predicts mortality of only 5% when heat stroke patients are managed properly [10]. A recent review of 34 elderly patients with classic heat stroke revealed 18% mortality. Seventy-three percent recovered without sequelae, and 9% had some residual neurologic deficit.

Although patients with temperatures as high as 46.5°C have survived without sequelae [71], mortality is increased with premorbid debility and higher maximal temperatures [44]. When ventricular fibrillation, DIC, or coma last more than 6 to 8 hours, or high lactate levels complicate hyperthermia, mortality is predictably increased. A continued rise in growth hormone levels despite therapy has been reported to be associated with a worse prognosis [72].

With respect to morbidity, neurologic function usually rapidly returns to normal after restoration of eutherma; however, some patients may be left with a mild cerebellar disorder [73]. Hepatic and renal failure in mild and moderate cases completely resolves. Moderate muscle weakness may persist for several months among patients with severe muscle damage.

Although it has not been proven, patients who have experienced
hyperthermic crises are at increased risk of recurrence upon exposure to similar heat stresses.
MALIGNANT HYPERThERMIA

MH is a drug- or stress-induced hypermetabolic syndrome characterized by vigorous muscle contractions, an abrupt increase in temperature, and subsequent cardiovascular collapse. MH occurs, on average, in 1 in every 50,000 to 150,000 adult patients given anesthesia [71, 74]. This may be an underestimation because of unrecognized, mild, or atypical reactions owing to variable penetrance of the inherited trait. MH occurs in all ethnic groups, more frequently in males than females (2:1), children under the age of 19 accounts for about 52% of reported events, 21% have had previous uneventful anesthesia, and 76% have no family history of MH [94, 95].

Cause and Pathogenesis

The cause of the temperature increase in MH is because of sustained muscle contraction over time, generating more heat than one can dissipate. When exposed to various drugs, muscles may develop sustained or repeated contractions (Table 185.3). Current evidence indicates that patients with MH have a defect in calcium metabolism in skeletal muscle cell membranes [76–79]. In most cases, a defect in the ryanodine receptor (RYR1) results in release of calcium from the sarcoplasmic reticulum, resulting in muscle contraction and heat generation [80]. This leads to hydrolysis of adenosine triphosphate and the activation of catabolic pathways, hepatic and muscular glycogenolysis, and catecholamine-induced accelerated turnover of substrates and the production of lactate.

Although halothane and succinylcholine are involved in more than 80% of cases, MH has developed after the use of many other agents as well (see Table 185.3). Heat stress, vigorous exercise, excitement, anoxia, viral infections, and lymphoma have also been reported to trigger MH [81,82]. Some data suggest that conditions of ischemia or hypoxia are the common triggers to hyperthermia in susceptible individuals.

The hyperthermic reaction to anesthetics is not allergic in nature; patients may have received the same anesthetic previously or may be exposed later without developing a reaction. There is little evidence that impaired heat dissipation or altered hypothalamic regulation is instrumental in producing acute hyperthermia in these patients. However, sympathetic activity and heat dissipation may be abnormal during vigorous exercise [83].

Pathophysiology

MH-susceptible patients have genetic skeletal receptor abnormalities, allowing excessive calcium accumulation in the presence of certain anesthetic triggering agents. During an episode of MH, downstream effects from unregulated passage of calcium from the sarcoplasmic reticulum into the intracellular space lead to sustained muscle contraction and production of more heat than the body can dissipate. Temperature levels above 42°C lead to similar physiologic and pathologic changes described for patients with exertional heat stroke [84]. DIC, hepatic failure, seizures, ventricular dysrhythmias, and electrolyte abnormalities are more common and severe than in heat stroke.

Vigorous muscle contracture at the onset of MH almost immediately
precipitates a severe metabolic acidosis, with increased CO₂ production and compensatory hyperventilation. High elevations of creatinine kinase, lactate dehydrogenase, and aldolase are present [65] and reflect ongoing rhabdomyolysis. Hyperkalemia follows within minutes to hours [76]. Renal failure frequently occurs in MH, most likely secondary to myoglobinuria. Dehydration and low cardiac output do not contribute until later. The degree of hypocalcemia, hypophosphatemia, and hyperkalemia varies with the duration and peak of hyperthermia and degree of secondary myonecrosis. All three are more severe in MH than in heat stroke. Direct thermal injury producing cerebral edema and cerebral hemorrhage can result in coma. Seizures occur among most uncontrolled cases. DIC is a nearly universal finding [85]. Initially, volume status is normal because little volume has been lost in sweat. Cardiac output increases to meet metabolic demands and in response to the vasodilation of muscle beds. Sinus tachycardia, supraventricular tachyarrhythmias, and ventricular fibrillation occur soon after temperature exceeds 40°C. Tissue hypoxia, acidosis, and hyperkalemia make ventricular arrhythmias common. Because higher maximal temperatures are usually seen in MH, hepatic failure and GI tract bleeding are more frequent than in heat stroke [85]. Among survivors, hepatic necrosis and cholestasis peak in 2 to 3 days and may be severe.

**Diagnosis**

The metabolic predisposition to MH appears to be inherited in an autosomal dominant fashion, with variable penetrance and expressivity. Although multiple screening strategies have been attempted [76,86–89], tests using caffeine or halothane stimulation of excised muscle are the standard screening tests recommended by the MH Association of the United States [90]. Their false-positive rate is near 10% and false-negative rate is near zero [91]. Because there is no noninvasive test suitable for screening the general population, screening of family members of proven cases remains the best method of identifying susceptible individuals before hyperthermic crisis occurs. RYR1 gene mutation analysis of cells from buccal samples may help identify high-risk individuals. Only 25% of those susceptible have an identified mutation. Although an identified mutation would suggest susceptibility, the absence of a mutation does not rule it out [92,93].

**Clinical Signs**
Early signs of hyperthermic crisis vary with the anesthetic agent administered but include masseter muscle contracture after the administration of succinylcholine, muscle rigidity, sinus tachycardia, supraventricular tachyarrhythmias, mottling or cyanosis of the skin, increased CO₂ production resistant to increasing minute ventilation, and hypertension. Hyperthermia is typically a late sign during an acute crisis, but it may be rapidly followed by hypotension, acidosis, peaked T-waves on the electrocardiogram owing to hyperkalemia, and malignant ventricular arrhythmias [85], as well as myoglobinuria and excessive bleeding. In one case report, desaturation measured by oximetry preceded temperature elevation by 40 minutes [96].

Two signs may be helpful in making a prehyperthermic diagnosis: increased end-tidal CO₂ and masseter spasm [97–103]. Monitoring of end-tidal CO₂ is recommended for all anesthetic procedures and is mandatory for patients at risk of MH [91,94,95]. Severe masseter spasm after succinylcholine has been recognized as an early warning sign of MH; however, the decision to discontinue anesthesia for patients with succinylcholine-induced spasm remains controversial [100–104]. If surgery must be continued, dangerous triggering anesthetics should be avoided, dantrolene should be given or at least be immediately accessible, and temperature and end-tidal CO₂ should be monitored.

**Differential Diagnosis**

Because MH occurs almost exclusively in the perioperative setting, the differential diagnosis is more limited than that for heat stroke (see Table 185.2) [104]. Endocrinopathies and drug reactions, not infection, are the most frequent diseases in the differential diagnosis. Thyroid storm and pheochromocytoma may be very difficult to distinguish from MH in the anesthetized patient [105]. Thyroid storm is now infrequent, owing to preoperative thyroid function test screening and prophylaxis of patients at risk. Dantrolene in doses used for MH has been shown to decrease temperature in perioperative thyroid storm [106]. The temperature rise in pheochromocytoma is typically much slower than that in MH [107]. Hyperthermia, owing to narcotic administration in patients taking monoamine oxidase inhibitors, also must be considered.

**Treatment**

Dantrolene, a hydantoin derivative, acts by uncoupling the excitation–contraction mechanism in skeletal muscle and lowering myoplasmic calcium. This action takes place directly at the RYR1 receptor [108]. Dantrolene used for less than 3 weeks rarely causes toxicity [109]. In an
acute crisis, 1.0 to 2.5 mg per kg of fresh dantrolene should be administered intravenously every 5 to 10 minutes. Effects may be seen 2 to 3 minutes after injection. Although cases that required 42 mg per kg have been reported [110], most authorities advise not to exceed 10 mg per kg [75,76,110,111]. The half-life of action is approximately 5 hours [76], and because relapse may occur, oral or IV dosages of 1 mg per kg IV or 2 mg per kg by mouth every 6 hours should continue for at least 24 to 48 hours [76]. Oral dantrolene may be substituted once the patient is alert [112], given its bioavailability. With dantrolene, temperatures often rapidly decrease; without it, they may increase 1°C to 2°C every 15 minutes [95,97,110].

In the United States, there are two types of dantrolene preparations. The older form is a lyophilized powder in a 20-mg vial containing 3 g of mannitol and sodium hydroxide, and each 20 mg vial requires mixing with 60 mL of sterile water requiring additional personnel to assist in drug preparation given that for an initial bolus in a 70-kg patient, nine vials are needed. It is however the least expensive. The new dantrolene formulation (Ryanodex) is rapidly dissolved, supplied in 250-mg vials, reconstituted with only 5 mL of sterile water, and warming is not needed. It is double the price but because it is hyperconcentrated, blood concentrations are achieved faster, it requires less time, and fewer staff to prepare the vial, making it clinically more efficient to deliver.

Because even minute quantities of the triggering agent may continue to produce the syndrome, anesthesia should be immediately stopped, and the anesthesia apparatus, tubing, and ventilation equipment should be immediately changed.

As with heat stroke, iced saline, gastric or peritoneal lavage, evaporative cooling, and infusion of chilled electrolyte solutions may be helpful. Aggressive management with cardiopulmonary bypass with external cooling of the blood may be necessary when dantrolene fails to slow down thermogenesis promptly [113]. When patients respond to therapy quickly, before severe temperature elevation occurs, only minimal supportive measures may be necessary. Once temperature exceeds 41°C, complications are widespread and patients frequently require long-term intensive care unit (ICU) support.

Ventricular fibrillation with subsequent cardiac collapse is the most common cause of death for the early stages of the syndrome. Procainamide should be given to all patients prophylactically as soon as MH is diagnosed [76]. Procainamide acts to increase the uptake of calcium from the myoplasm directly and in early stages may help reduce
hyperthermia. Administration of digitalis should be avoided because of the increased likelihood of hyperkalemia. Hypotension should be treated with saline infusion and isoproterenol. Avoid dopaminergic and α-agonists because they reduce heat dissipation owing to peripheral vasoconstriction. Seizures often occur among MH patients. Prophylactic treatment with phenobarbital is strongly recommended because seizures may increase heat production, metabolic acidosis, and hypoxia. Arterial blood gas values should be adjusted for temperature. Mannitol and furosemide may be needed to promote continued urine output and may reduce the likelihood of cerebral edema and acute tubular necrosis. The serum potassium level increases over several hours and is treated with polystyrene sulfonates. Hepatic failure and DIC require supportive treatment. With prolonged supportive care, hepatic, renal, and neurologic functions typically normalize. Muscle weakness, however, may last for months.

**Prognosis**

With current management techniques, mortality resulting from MH should be less than 30% [75]. In one review, prompt dantrolene therapy in cases of confirmed MH resulted in a 100% survival rate [25].
NEUROLEPTIC MALIGNANT SYNDROME

Neuroleptic malignant syndrome (NMS) is a life-threatening neurologic emergency associated with the use of neuroleptic agents and is characterized by hyperthermia, muscular rigidity, dysautonomia, and altered mental status. Most current knowledge is derived from case reports rather than systematic study. Since the NMS was first described in 1968 [114], fewer than 3,000 cases have been reported in the world’s literature, and most are from the 1980s and 1990s.

Incidence rates for NMS vary from 0.02% to 3% among patients taking neuroleptic agents [115–120]. The variation reflects differences among the populations sampled, surveillance methods, and definitions of the disease. NMS has been described for all age groups, and it is more common in men by twofold [115,162,163]. The larger muscle mass in men may predispose to the development of hyperthermia. There is, however, no difference in mean maximal temperature between men and women. A case control study has shown that environmental temperature does not affect the incidence of the NMS but several factors do: total neuroleptic dose; mental retardation; intramuscular administration of a neuroleptic, psychomotor agitation, or increasing dose; or recent introduction of a neuroleptic drug [164]. Early estimates of mortality were as high as 30% [121]. Incidence also appears to be declining [122]. Mortality rates since 1986 has fallen to less than 12% [123]. Two prospective series reported 24 and 68 cases, with mortality rates of 0% [124] and 5% [125], respectively.

Cause and Pathogenesis

The cause of NMS is unknown. An animal model for NMS has been developed, but it does not correspond with the human syndrome [115]. Because the syndrome is found among patients on dopamine receptor blockade agents or inpatients after withdrawal of dopaminergic agents (Table 185.4), dopamine receptor blockade is considered to be central to most theories of its pathogenesis. Butyrophenones [126–140], phenothiazines [126,128,131,134,141,142], thioxanthenes [143–145], and dibenzoxazepines [146] are believed to act as dopamine receptor–blocking agents. Atypical antipsychotics, such as risperidone [147], molindone [148], clozapine [149], and fluoxetine [150], and dopamine blockers used to treat GI tract disease, such as metoclopramide and domperidone [151], have also caused the syndrome. The incidence of the syndrome with the newer atypical antipsychotics has not changed [152]. Drugs acting at the D2 dopamine–binding sites appear to have the greatest potential for causing the syndrome. Most cases occur among
patients taking butyrophenones or piperazines, agents with a high incidence of extrapyramidal reactions. The rate of increase in dose appears more important than the maximal dose achieved [123]. Dopamine-depleting agents such as tetrabenazine and α-methyltyrosine produced NMS in a patient with Huntington’s disease [121]. Abrupt withdrawal of levodopa (L-dopa), dopa-carbidopa, or amantadine produced the syndrome in patients suspected of having Parkinson’s disease [153–155]. Initiation of metoclopramide therapy has produced the syndrome, presumably owing to alteration in central dopaminergic tone [156–158].

An alternative theory is that rigidity and muscle damage represent a primary effect on the peripheral muscle system, possibly from direct changes in muscle mitochondrial function. This is because of either a primary muscle defect or a direct toxic effect by neuroleptics. A peripheral muscle abnormality is possible because the sarcoplasmic calcium concentration is higher among patients who have had the syndrome [125], resolves with nifedipine use [159], and has been reported to be triggered by hypoparathyroidism [160]. However, the muscular effects are typical of the parkinsonian type of extrapyramidal reactions, frequently seen at low therapeutic doses soon after treatment begins, and the muscle spasm resolves with the use of centrally acting dopaminergic agents such as bromocriptine, amantadine, and L-dopa.

Hyperthermia results from an increase in endogenous heat production, impaired heat dissipation, loss of voluntary temperature regulation, and possibly an elevation of the hypothalamic set point. This suggests that there may also be a disrupted modulation of the sympathetic nervous system. The fact that the degree of temperature increase varies directly with the severity of rigidity evident on examination strongly suggests that muscle contracture is responsible for increased thermogenesis [126]. A decrease in muscle rigidity by uncoupling contraction with dantrolene or by paralysis with succinylcholine results in a decrease in temperature [161]. Impaired heat dissipation from the anticholinergic-induced hypohidrosis of neuroleptics may also occur. The most likely hypothesis is that regulatory reflexes remain intact, but muscle rigidity from the hypothalamus and subsequent increased thermogenesis exceed dissipative capacity.

Familial clusters of NMS suggest a genetic predisposition. Genetic studies have shown that the presence of a specific allele of the dopamine D₂ receptor gene is overrepresented in NMS patients. This allele is associated with reduced density and function of dopamine receptors as well as decreased dopaminergic activity and metabolism [239].

Clinical Presentation

Onset of symptoms may occur within hours after the initial neuroleptic treatment or up to 4 weeks later [162]. Among the majority of cases, onset occurs within 1 week from initial neuroleptic drug use, and 88%
occur within 2 weeks of a dosage increase of an already prescribed neuroleptic agent [162]. Most reported cases have occurred among patients with underlying neuropsychiatric disorders. Most cases have a slow progression of symptoms over at least 24 to 48 hours and last 2 weeks after stopping the inciting drug [171].

Early symptoms include dysphagia or dysarthria, pseudo-Parkinsonism, dystonia, or catatonic behavior. In one series, 96% of patients demonstrated rigidity, 92% of patients demonstrated tremor, and 96% of patients demonstrated muteness or hypophonia in the 48 hours before diagnosis [171]. Rigidity precedes hyperthermia in 59% of patients, is concurrent in 23%, and is subsequent in only 8%. Changes of mental status or rigidity are the presenting symptoms in 82% of patients [172]. Autonomic signs of hypermetabolism such as diaphoresis, tachycardia, changes in blood pressure, and tachypnea, reflect efforts to dissipate the thermogenesis of muscle contracture and to expel CO₂ effectively. Peak temperatures are reached within 48 hours after the onset of symptoms in 88% of patients [124]. Temperatures may reach as high as 42.2°C [132] but are typically lower: 53% are more than 40°C and 13% are higher than 41°C [124]. Rectal or core, rather than oral, temperatures are needed to ensure accuracy (see Chapter 26). Elevations in creatinine kinase and transaminase levels and leucocytosis parallel the body temperature.

Complications

Because of the relatively low maximal temperatures—39.9°C, on average [163]—among patients with NMS compared with those of patients with heat stroke and MH, it is not surprising that direct thermal injury occurs less often. Only 40% of patients have temperatures above 40°C [165]. The complications of NMS are summarized in Table 185.5. Cardiovascular collapse, renal failure, and electrolyte abnormalities are less common and less severe than in classic heat stroke.

</tbody>
</table>
Rhabdomyolysis, most probably secondary to hyperthermia and muscle rigidity, is frequently seen, with typical creatinine kinase elevations in the range of 1,000 to 5,000 IU. Although rhabdomyolysis is usually mild, creatinine kinase elevations of greater than 100,000 IU have been reported [145,166,167] and may occur in up to one-third of patients [124]. Prolonged muscle weakness or dysfunction in survivors has not been described.

Renal failure occurs in 9% to 30% of patients [124,162]. Proteinuria occurs in up to 91% of patients [124]. Renal failure is owing to myoglobin-induced acute tubular necrosis and the dehydration that results from diaphoresis. Renal dysfunction of most patients is transient and mild and, even among cases with acute tubular necrosis, and may return to premorbid values after brief periods of dialysis support [129]. Mortality among renal failure patients, however, may be as high as 56% [123].

NMS has been associated with worsening of underlying psychiatric conditions, amnesia, cognitive impairments, and peripheral neuropathy [168,169]. Coma is not uncommon among severe cases. Grand mal seizures have rarely been reported [129,144]. The electroencephalogram (EEG) typically is normal or shows nonspecific diffuse slowing [124]. CT scans of the brain are normal in 95% of patients. CSF analysis after lumbar puncture is normal in 97% of patients, showing an elevated protein level in the other 3% [162,170]. In one case, an MRI scan revealed hyperintensity of the occipitoparietal white matter [171]. Pathologic examinations of patients at autopsy have revealed no specific lesions [154].

Although death from cardiovascular collapse has been reported [126], specific cardiac abnormalities have been poorly described. There is no evidence that severe atrophy, heart block, or congestive heart failure occurs frequently in NMS.

Hematologic alterations are mild. The white blood cell count is elevated among 78% of cases [124,162], usually less than 20,000 cells per mm$^3$, and rarely exceeding 25,000 cells per mm$^3$. Elevation may be caused by hemoconcentration and catecholamine release. Platelet count is elevated in 56% of patients [124]. A hemolytic coagulopathy, possibly DIC, has been infrequently reported [132]. Deep venous thrombosis or antemortem embolic phenomena are not reported in the English literature. Thrombotic events, when they do occur, may be a result of the patient’s immobility owing to coma and muscle rigidity rather than to any temperature-mediated change.

Mild elevations of lactate dehydrogenase, serum glutamic oxaloacetic acid transaminase, serum glutamic pyruvic transaminase, and alkaline phosphatase are common.
Pulmonary complications occur because of the extrapyramidal actions of the neuroleptics. Dysphagia [126] and sialorrhea can lead to aspiration pneumonias and necessitate intubation in 13% to 21% of patients [124,131,132,134,140,145,153,161–163,166] and are probably the most serious frequent sequelae of NMS.

Diagnosis

There is no diagnostic test for NMS, the laboratory abnormalities help confirm and rule out other conditions or help trend the patients for complications. MRI and CT imaging of the brain are typically normal but can show diffuse cerebral edema with severe metabolic derangements. CSF is typically normal but may have nonspecific protein elevation in 3% of the cases [162,170]. EEG is helpful to rule out nonconvulsive status epilepticus. NMS patients have generalized slow-wave activity. An international multispecialty consensus group published diagnostic criteria for NMS in 2011 [240]. This criterion requires independent validation before its use can be recommended in clinical practice.

Differential Diagnosis

A thorough examination and diagnostic evaluation for other causes of hyperthermia should be conducted (see Table 185.2). In one series, all patients referred to an ICU with a suspicion of NMS had another diagnosis that would explain fever [119]. Because many patients taking neuroleptic agents develop extrapyramidal side effects and few cases of hyperthermia are a result of NMS, other more common causes of hyperthermia (e.g., meningitis or streptococcal pharyngitis) are more likely. Appropriate cultures, chest radiograph, lumbar puncture, and physical examination are mandatory. Patients without classic symptoms are more likely to have another cause of hyperthermia [173].

Catatonia, heat stroke, MH, and hyperthermic reactions to other drugs may occasionally be confused with the NMS. Acute lethal catatonia presents with psychotic excitement and automatisms a few weeks before motor deficit [174]. Laboratory values are typically normal. The treatment and prognosis for these patients remain unclear [163,175,176]. If rigidity and hyperthermia subsequently develop in a catatonic patient, however, the development of NMS should be presumed and all neuroleptic agents should be stopped. If catatonia has been induced or exacerbated by neuroleptics, withdrawal of the neuroleptic drug should aid in clarifying the diagnosis.
Heat stroke must be considered when temperature elevation develops in a patient taking neuroleptics during periods of high ambient temperature or after vigorous exercise. Unlike NMS, however, heat stroke is usually accompanied by flaccid obtundation, and muscle rigidity is rare.

MH resembles NMS in that both conditions have increased thermogenesis secondary to muscular rigidity as well as similar laboratory findings, and both respond to dantrolene. In most cases, an adequate history should clearly separate the two syndromes; MH results from the use of different agents (compare Tables 185.3 and 185.4). Moreover, the symptoms of MH are much more rapid in onset and more severe. Extrapyramidal symptoms are also very unusual in MH. In the rare circumstance in which the two syndromes cannot be distinguished, attempts at paralysis with curare or pancuronium may aid diagnosis. These agents produce a flaccid paralysis in NMS but should have no effect on the postsynaptically mediated muscle contracture of MH.

Serotonin syndrome (SS) is the most commonly diagnosed related disorder and is caused by the use of selective serotonin reuptake inhibitors. It has a similar presentation and is difficult to distinguish from NMS. Typical features in these patients that are not often seen in NMS are shivering, hyperreflexia, myoclonus, and ataxia. Nausea, vomiting, and diarrhea are also a common part of the prodrome in SS and are rarely seen in NMS.

Idiosyncratic drug reactions and anaphylaxis accompanying severe hyperthermia may usually be diagnosed by their distinct clinical presentations. Monoamine oxidase inhibitors may produce hyperthermia, especially when administered with meperidine, linezolid, or dextromethorphan [177–180]. In patients with neuropsychiatric disorders who are receiving neuroleptic agents and monoamine oxidase inhibitors, MH may result from either agent. In these cases, both agents should be stopped. Therapies for NMS, such as bromocriptine or L-dopa, however, are contraindicated in these patients because of their recent use of monoamine oxidase inhibitors.

**Treatment**

Stopping the causative agent is the most important treatment followed by supportive care. The goal of treatment for NMS is to reduce the temperature, reverse extrapyramidal side effects, and prevent sequelae. Supportive care is essential in the ICU [181] and includes maintaining cardiorespiratory stability, and euvoletic state with crystalloid IV therapy (and possibly urine alkalinization to reduce renal failure from rhabdomyolysis) [126], lowering fever using cooling blankets (or more aggressive measures including ice water gastric lavage) and possibly
acetaminophen or aspirin, lower the blood pressure if markedly elevated (clonidine is effective and possibly nitroprusside), prophylactic intubation if sialorrhea is present, prevention of deep vein thrombosis, and the use of benzodiazepines to control agitation [191].

Specific agents used to decrease thermogenesis by reducing muscle contracture include dantrolene, curare, pancuronium, amantadine, bromocriptine, and L-dopa (Table 185.6). The use of these agents is based upon case reports and clinical experience, not from clinical trials. The efficacy is unclear and disputed [124,162,181–182,192–197].

Dantrolene reduces thermogenesis by uncoupling muscle contracture at the membrane level and in doses as small as 1 mg per kg may result in a temperature decrease of 1°C to 2°C within hours [135,136,140,183]. Dantrolene may also favorably alter CNS dopaminergic metabolism [184]. Although doses of up to 10 mg per kg have been used, current practice would recommend doses of 1.0 to 2.5 mg per kg IV every 6 hours until a dose of 100 to 300 mg per day by mouth can be given [185,186]. Dantrolene therapy does carry a risk of hepatotoxicity, but in patients with temperatures greater than 40°C, its use is specific and should be beneficial. Paralysis with curare or pancuronium should produce a similar prompt decrease in temperature, but this treatment necessitates mechanical ventilation and extensive support [161]. Bromocriptine, amantadine, and carbidopa/L-dopa increase central dopaminergic tone; this decreases the central drive, reducing muscular rigidity and thermogenesis. These agents also are beneficial in that they act directly to reduce extrapyramidal side effects. Prompt decreases in temperature have been reported after the use of 2.5 mg of bromocriptide three times per day [134,138,167,187], 100 or 200 mg of amantadine twice per day [139,188], or 10 to 100 mg of carbidopa/L-dopa three times per day [127,155].
Failures of these therapies, however, have also been published [141, 143, 153, 187]. The appropriate dosing remains an important question. Some authorities have advocated bromocriptine doses as high as 60 mg per day [185]. Use of a centrally acting dopamine agonist is warranted when NMS occurs because of withdrawal of anti-Parkinson’s agents. The use of dantrolene, bromocriptine, and amantadine has yet to be shown to reduce mortality significantly [123]. Electroconvulsive therapy has been successful for several patients [131, 132, 189, 190] and is the only therapeutic modality that may be used successfully to treat simultaneously hyperthermia, the extrapyramidal side effects, and the underlying neuropsychiatric disorder for which the neuroleptic drug was prescribed. Because of several reports of cardiovascular collapse among patients undergoing electroconvulsive therapy, this therapy should be given only to patients at low risk of cardiovascular disease who have failed other therapy.

Less-specific agents, such as diphenhydramine, benztropine, diazepam, and trihexyphenidyl, have been used successfully [127, 130, 134, 137, 139, 146] but more typically have not been helpful [121, 134, 140, 141, 161, 187, 188].

Prognosis

Most episodes resolve within 2 weeks. The average time to recovery with supportive care is 9.6 days [165]. Typically, ICU stay is prolonged owing to the frequency of complications and slow response to therapy. Although dopaminergic therapy lowers the mean time to response from 6.8 to 1.1 days [199], the mean time to recovery is long—13 days when the syndrome results from nondepot neuroleptics and 26 days for depot neuroleptics [162]. One patient receiving haloperidol decanoate was symptomatic for months [200]. Rechallenge with neuroleptics may cause the syndrome to recur, but this occurs much more frequently during the first 2 weeks [201, 202], concomitant use of lithium, high potency drugs, and parenteral neuroleptics.

Although mortality rates as high as 20% to 30% have been reported [115], this rate can probably be reduced to less than 10% with appropriate support and treatment. Age and sex do not appear to influence mortality. Mortality rate does appear to be influenced by peak temperature, inciting neuroleptic drug, and renal failure. No death among patients with maximal temperatures lower than 40°C has been reported. Haloperidol is statistically less likely to result in death than other neuroleptics [123]. Death has been reported as a result of cardiovascular collapse [126], pneumonia [131, 161], renal failure [129, 145], and hepatic failure [145]. More than 57 cases of acute renal failure caused by NMS have been reported [198]. The development of renal failure is particularly ominous;
in some series, 46% of patients with myoglobinuria and 56% of those with renal failure died [123].
Most of our knowledge about DIH is derived from case reports. Numerous drugs have been suggested to cause hyperthermia. Drugs that blunt cardiovascular performance, such as β-blockers, or alter heat dissipation, such as chlorpromazine, are widely used and can contribute to temperature elevation. These drugs rarely result in clinically significant hyperthermia without some other precipitant. Patients on regimens of such agents typically present with heat stroke. This section focuses on drugs that independently produce significant elevations of temperature (Table 185.7).

**TABLE 185.7 Drugs that may Cause Hyperthermia and/or Serotonin Syndrome**

- Monoamine oxidase inhibitors
  - Phenelzine = Nardil
  - Tranylcypromine = Parnate
  - Linezolid
- Serotonin releasers
  - Amphetamines
  - Ecstasy (MDMA)
  - LSD
- SRI
  - Citalopram = Celexa
  - Fluoxetine = Prozac
  - Fluvoxamine = Luvox
  - Paroxetine = Paxil
  - Sertraline = Zoloft
- Tricyclics:
  - Clomipramine = Anafranil
  - Imipramine = Tofranil
  - Venlafaxine = Effexor
- Analgesics:
  - Tramadol
  - Methadone
  - Dextromethorphan
Commonly abused street drugs may result in severe hyperthermia without other pharmacologic or environmental stimuli. Temperature elevation accompanies phencyclidine use in 2.6% of cases [204]. Temperatures as high as 41.6°C have been reported [205]. Amphetamine use may result in temperatures higher than 43°C [205,206]. Although ecstasy (3, 4-methylenedioxymethamphetamine [MDMA]) has resulted in fatal hyperthermia, use is usually associated with a more mild temperature elevation [207]. Hyperthermia (temperatures greater than 37.5°C) was more prevalent (36%) in patients admitted to emergency departments because of overdose of paramethoxyamphetamine than MDMA [208]. Although all these drugs have a low incidence of producing severe hyperthermia, owing to the prevalence of their use, they may account for a large percentage of cases of hyperthermia presenting to an emergency department.

Common prescription drugs that alter central serotonin levels and lysergic acid diethylamine, a serotonin analog, may result in hyperthermia greater than 41°C [209]. These drugs may produce a characteristic constellation of symptoms now known as the serotonin syndrome (SS) [209–214]. Monoamine oxidase inhibitors and selective serotonin reuptake inhibitors may produce hyperthermia, especially when administered with meperidine or dextromethorphan [177–179], tricyclic antidepressant [177,215], or each other. Severe hyperthermia is rare. Increasingly, combinations of drugs that independently would not cause serotonin toxicity act in concert to result in hyperthermia and the SS [216]. For example, a postoperative patient who receives linezolid, a weak monoamine oxidase inhibitor, and tramadol, a weak serotonin reuptake inhibitor, may present with fever, confusion, and clonus. Tramadol, meperidine, fentanyl, dextromethorphan, dextropropoxyphene, pentazocine, brompheniramine, chlorpheniramine, and linezolid in combination with other drugs may cause fever and the SS [180]. In addition, abrupt withdrawal of baclofen, especially after intrathecal administration, has resulted in severe sequelae including hyperpyrexia and potential multiorgan failure and death [180].
Aspirin receives mention as a cause of hyperthermia secondary to increased metabolism, but few hard data are available on this association [217].

Pathogenesis

These drugs are thought to cause hyperthermia as a result of muscular contracture or hypermetabolism. Virtually, all case reports of DIH mention increased muscle tone, rigidity, or tremor. Cocaine, amphetamine, phencyclidine, and hallucinogens appear to produce hyperthermia by centrally and peripherally inducing vigorous muscle contractions [218,219]. Repeated cocaine use may elevate temperature by depletion of postsynaptic dopamine [218].

Many drugs such as tricyclics, amphetamines (paramethoxyamphetamine, MDMA), monoamine oxidase inhibitors, and the serotonin reuptake inhibitors may elevate CNS serotonin, resulting in hyperthermia [177,179,219–221]. Buspirone, serotonin agonists, lithium, and carbamazepine stimulate postsynaptic serotonin receptors. Monoamine oxidase inhibitors increase serotonin release and inhibit serotonin metabolism [222]. Selective serotonin reuptake inhibitors, dextromethorphan, and meperidine inhibit serotonin reuptake and, in susceptible patients, increase already high serotonin levels and trigger a hyperthermic crisis [200]. In many patients, combination drug therapy contributes to triggering the syndrome. In general, a 2-week, drug-free period after stopping a monoamine oxidase inhibitor before starting a selective serotonin reuptake inhibitor is indicated. Any opiate may trigger the syndrome when another drug already predisposes the patient.

Some patients may exhibit exertional heat stroke, in that they are frequently found running in an agitated or confused manner. Almost all suffer from loss of voluntary control of temperature.

Status epilepticus frequently accompanies DIH but is unlikely to contribute to hyperthermia, in that status epilepticus is rarely associated with significant temperature elevation in the absence of drug use [223].

DIH reactions are idiosyncratic and infrequent in comparison with the total number of persons using the drug. It can occur by IV, enteral, or nasal insufflation usage, and after low-dose use and massive overdose [224].

Pathophysiology
The pathophysiology of DIH is most similar to that of exertional heat stroke or MH. In the SS, direct stimulation of the 5-HT$_{1A}$ and 5-HT$_2$ receptors in the raphe nuclei may directly result in hyperthermia. Rise in temperature is frequently rapid, and multiple organ failure rapidly ensues with prolonged elevation of temperature. Patients, however, may also be affected by the direct toxic action of the drug, and it may be difficult to separate the sequelae of hyperthermia from those of direct drug toxicity. Amphetamine overdose, for example, may result in severe rhabdomyolysis, DIC, and renal failure at temperatures less than 40°C. Hyperthermia can be assumed to have the same physiologic sequelae in these patients as others, but prompt correction of temperature may not be adequate to ensure survival.

**Diagnosis**

In most case reports, patients are described as agitated, hyperexcited, and diaphoretic and have increased muscle tone. Because nonexertional heat stroke is uncommon in youth, hyperthermia at a young age always suggests possible drug intoxication. The diagnosis of DIH should be considered mostly when the patient is young, is an outpatient, has not engaged in recent heavy exertion, has a history of drug abuse, or is on a drug or combination of drugs that may result in the SS.

Patients with the SS typically display tremor, hyperreflexia, myoclonus, tachycardia, diarrhea, confusion, and diaphoresis [210–214]. SS should be suspected and treated whenever patients have spontaneous clonus and are on a serotonergic agent. Nausea and diarrhea are atypical in NMS and may help suggest the SS in complicated cases [225]. The onset of symptoms is within 2 hours of medication ingestion in 50% of cases and within 24 hours in 75% of cases [222]. Myoclonus or rigidity is present in 50% of cases, and mental status changes in 40% of cases. Severe hyperthermia occurs in approximately one-third of cases [211]. Diagnosis may be confirmed by toxicologic screen or history.

**Treatment**

For all cases, treatment should be directed at minimizing the toxicity of the causative drug. Suspected offending drugs should be discontinued. Treatment of hyperthermia should be symptomatic and directed at the underlying physiology. Treatment in general parallels that for exertional heat stroke and is extensively outlined in that section. Evaporative cooling and external cooling with ice are the preferred methods of cooling and should be instituted in any patient with a temperature above 39°C. Many patients may be dehydrated from diaphoresis and require volume replacement. As for MH and exertional heat stroke, hyperkalemia,
acidosis, and myoglobinuria demand careful attention. Because the temperature appears to be generated from muscular contraction, paralysis or use of dantrolene would appear to be useful therapy. Paralysis has been effective in several cases. Paralysis and support with mechanical ventilation should be considered in any patient with a temperature above 40°C not responding promptly to symptomatic cooling. If therapeutic drug levels persist, rebound hyperthermia may occur when paralysis resolves.

When SS is suspected, therapy with benzodiazepines, propranolol, chlorpromazine, cyproheptadine, or postsynaptic serotonin blockers such as methysergide has been advocated, but clinical experience is minimal [218–220,226]. No study to date reports a systematic trial of therapy. Because hyperthermia may be mediated by central serotonin receptors, doses of cyproheptadine high enough to block central receptors, 20 to 50 mg, should be considered [227]. One regimen advises 12 mg by mouth or nasogastric tube then 4 to 8 mg every 4 to 6 hours [216].

Prognosis

Hyperthermia owing to amphetamine overdose appears to be well tolerated, with 10 of 11 patients reported in the literature surviving [205,206,228,229]. Hyperthermia in cocaine overdose is frequently accompanied by renal failure [224,230,231], DIC [231,232], and seizures [231,232] and several fatalities [224,231–233] have been reported. Survival despite high temperature has been recorded as well [224,230,234]. Phencyclidine with hyperthermia has resulted in renal failure [235], respiratory and liver failure with coma, and subsequent death [236].

Death and serious morbidity caused by SS appear to be rare [208]. No large series involving significant hyperthermia have been reported, and death and cure with appropriate treatment have been reported [179]. Because severe hyperthermia would likely signify a much more severe case than usual, the physician should always consider the patient at risk of death and ICU level care would always be warranted.

Table 185.8 compares the distinguishing characteristics of the hyperthermic syndromes. Advances in hyperthermia based on randomized, controlled trials or meta-analyses of such trials are given in Table 185.9.

### TABLE 185.9 Advances in Management of Hyperthermia Based on Randomized Controlled Trials

- No randomized clinical trials have been conducted comparing the effectiveness of different cooling methods for any hyperthermic syndrome [237].
- Dantrolene sodium is ineffective in heat stroke [64]. Dantrolene did not alter survival in heat stroke [65].
- There are no other randomized studies involving the treatment of heat stroke or malignant hyperthermia or drug-induced hyperthermia.
- In neuroleptic malignant syndrome, treatment with dantrolene and bromocriptine may offer no advantage over supportive care [176].
- Solu-Medrol may benefit patients with neuroleptic malignant syndrome owing to withdrawal from Parkinson’s medications [182].
HYPERTHERMIA AND FEVER CONTROL AFTER BRAIN INJURY

Fever among neurocritical care patients is frequent and often results in an adverse neurologic outcomes. Morbidity and mortality are increased among patients who have ischemic brain injury, intracerebral hemorrhage, and cardiac arrest. Fever appears to have a longer impact after subarachnoid hemorrhage and traumatic brain injury. New techniques (see hypothermia Chapter 67) have made treatment of fever and maintaining normothermia possible.
ACKNOWLEDGMENT

The authors wish to thank Dr. Frederick J. Curley for his efforts in coauthoring earlier editions of this chapter upon which much of the newer information has been added.

CARDIOVASCULAR PROBLEMS AND CORONARY CARE
AKSHAY S. DESAI • PATRICK T. O’GARA • DAVID A. MORROW
INTRODUCTION

There has been a striking evolution in the management of patients with cardiovascular diseases. Novel technologies and therapeutics have empowered clinicians to tackle conditions once considered untreatable. Created initially to support life-saving interventions following acute myocardial infarction (MI), Coronary Care Units (CCUs) began to rapidly proliferate in the 1960s, and were subsequently lauded for their ability to improve patient survival. Now heavily embedded in contemporary health care systems, the CCU has evolved into a Cardiovascular Intensive Care Unit (CICU)—home to patients with complex cardiac and noncardiac critical illnesses. This chapter highlights the historical underpinnings of the CCU and describes the evolving patient characteristics, disease severity, and care processes that have helped to shape the modern CICU.
FROM CORONARY TO INTENSIVE CARE

Historical Advances in the Management of Acute Myocardial Infarction

In a 1923 study entitled, “Thrombosis of the Coronary Arteries with Infarction of the Heart,” Dr. Joseph Wearn, a physician at the Peter Bent Brigham Hospital, described the course of 19 patients who survived an acute MI [1]. At that time, the condition was described as “one of the great rarities of medicine.” Given that it was “impossible to diagnose,” it was believed to be of little clinical import, and hence little effort had gone into improving either its evaluation or management. In fact, most afflicted individuals received little more than prolonged convalescence, and every effort was made to “spare the patient from bodily exertion.”

In the 40 years following the publication of Dr. Wearn manuscript, the incidence of death from coronary disease and acute MI steadily increased, becoming the most common cause of mortality in the United States (US) by the 1930s, and reaching a peak in the mid-1960s [2]. This epidemiologic shift was attributed largely to a decrease in death from other causes (i.e., infection) and a simultaneous increase in coronary atherosclerosis. Lifestyle changes, dominated by increasing tobacco use and an evolving diet, were implicated in this emerging epidemic, and the development of novel ways to diagnose and treat acute MI became a national priority.

The invention of the electrocardiogram (ECG) in 1902 by Dutch physiologist Willem Einthoven was a major step in that process [3]. Initially the ECG was celebrated for its ability to characterize electrical rhythm disturbances of the heart, but slowly gained prominence for its capacity to demonstrate particular waveform distortions in the setting of acute myocardial ischemia and infarction. Several decades later, William Kouwenhoven, an electrical engineer with no formal medical training, published data on the earliest form of cardiac defibrillation [4]. Since most of his seminal work was performed on animal models, it would take another decade for the first successful open cardiac defibrillation to be performed by Dr. Claude Beck on cardiac surgical patients at Case Western Reserve University. For patients suffering sudden death, this open defibrillation and cardiac massage became standard of care. The evolution of contemporary cardiopulmonary resuscitation and closed chest defibrillation soon followed from additional work by Guy Knickerbocker, Paul Zoll, and others [4].

With these advancements of resuscitation techniques, along with developments in cardiac monitoring (i.e., telemetry), clinicians were
finally equipped with tools to identify and rapidly treat the life-threatening sequelae of acute MI. As Desmond Julian, a senior registrar of the royal infirmary of Edinburgh, would later articulate, “many cases of cardiac arrest associated with myocardial ischemia could be treated successfully if all medical, nursing, and auxiliary staff were trained in closed chest massage, and if the cardiac rhythm of patients were continuously monitored by an ECG” [5]. This vision became the foundation for the development and subsequent rapid proliferation of CCUs throughout the world (Fig. 186.1) [6,7].

![Fig. 186.1](image)

**FIGURE 186.1** Prototypical design of the earliest Coronary Care Unit. A design of the Samuel A. Levine Cardiac Unit at Brigham and Women’s Hospital, Boston, MA [10]. Monitoring was carried out from the bedside units (M) and from two four-channel oscilloscopes visible from the central nursing station. A central monitoring room was employed for continuous tape recording.

One of the earliest CCUs, founded by Dr. Lawrence Meltzer in Philadelphia, was no more than a pair of adjacent rooms between which an early model defibrillator could be passed. Another, in Toronto, Ontario, emphasized arrhythmia surveillance with archetypal telemetry monitoring [8]. In general, nurses were empowered to act immediately and autonomously to resuscitate unstable patients. Despite their relatively narrow scope, early CCUs nonetheless were suggested to have had an enormous impact on survival. As an example, Killip and Kimball reported a decrease in mortality from 27% to 6% for acute MI patients cared for in the New York Hospital/Cornell Medical Center CCU [9]. Similar results were reported by others and led to a rapid proliferation of CCUs embedded within most large hospitals.
Shifting Care in the CCU—Addressing Complications of MI

In 1967, Lown and colleagues were credited with a paradigm shift in CCU care. These clinicians publicly bemoaned many of the challenges with MI management, noting in particular that there was little available with which to “alter the inexorable course of overwhelming shock or unyielding pulmonary edema,” so often contributing to postinfarction death. Although acknowledging that their CCU was “equipped, organized, and oriented to treat (fatal) rhythm disturbances,” they were one of the earliest to emphasize the staggering impact of cardiogenic shock and heart failure on mortality following MI. They called for a shift the focus of management in the CCU from resuscitation to the prevention of adverse events [10].

Lown’s appeal was addressed by several major advances in the 1960s and 1970s. The intra-aortic balloon pump (IABP), for instance, utilized counter-pulsation technology to support the failing heart, and could be employed as a means for treating cardiogenic shock. First used clinically in 1968 by Adrian Kantrowitz, the IABP enhanced coronary perfusion while decreasing left ventricular work [11]. In 1970, Swan and Ganz introduced their pulmonary arterial catheter which would have a major impact on the way critically ill cardiac patients were managed [12]. Though their device was not the first of its kind, it advanced CCU care because it could be inserted quickly at the bedside. Use of the Swan–Ganz catheter led to important new insights into cardiac hemodynamics, and altered our understanding of the complications of and treatments for acute MI.

This technology gradient continued to evolve with the introduction of echocardiography. First used in the 1950s in Europe, echocardiography was subsequently promoted in the US in the late 1960s by many practitioners, including Dr. Harvey Feigenbaum [13], who embraced this tool in the face of growing frustrations with the “tediousness and inaccuracies of catheterization techniques for the measurement of cardiac output, volumes, and pressures.” Echocardiography became increasingly more commonplace in the CCU and was championed for its ability to provide portable, rapid, and comprehensive information about a critically ill cardiac patient.

Additional Maturation of the CCU
A powerful endorsement of the CCU came from Goldman and Cook who attributed much of the declining morality seen from ischemic heart disease between 1968 and 1976 to the development of specific medical interventions, including the CCU [14]. Julian [15] and Reader [16] separately surmised that the steady decline of mortality among individuals 35 to 64 years of age within the US, Australia, and New Zealand may have been a direct effect of specialized CCU care. Similar support for the CCU could be found even after the introduction and validation of fibrinolytic therapy for acute MI, as treatment received in a CCU was still considered a major predictor of contemporary survival [17].

Although cardiologists became better equipped to treat MI, a condition once considered terminal, the population of patients admitted to the modern CCU concurrently changed substantially with the proportion of patients admitted to the CCU with MI declining. The population is more diverse, with greater representation of older, female, and minority patients. Patients admitted to CCUs are more likely to suffer from additional comorbid conditions, including chronic lung, liver, and kidney disease. Illness severity has worsened in parallel. Many CCUs have now evolved into intensive care units (ICUs) for patients with cardiovascular diseases. In a longitudinal study of nearly 30,000 patients admitted to a single-center CCU over a two-decade period, presenting disease severity increasingly worsened and the impact of noncardiovascular critical illness had intensified [18]. In response to these changes, many institutions have since accepted a new moniker for contemporary CCU care, and have begun to use the term “Cardiovascular Intensive Care Unit (CICU)” to reflect their broadened approach to the management of all critically ill cardiac patients. Figure 186.2 illustrates many of the key historical events that have been essential to the maturation of the CICU.

**FIGURE 186.2** Historical events key to the maturation of the contemporary Cardiovascular Intensive Care Unit (CICU).
UNDERSTANDING THE NEEDS OF TODAY’S CICU

Clinical research initiatives have been paramount in the field of cardiology, and have led to substantial improvements of outcomes for patients with cardiovascular diseases. Critically ill cardiac patients have also benefited from many of these advances. Examples include revascularization for cardiogenic shock [19], targeted temperature management for cardiac arrest [20], and the use of left ventricular assist devices (LVADs) for end-stage heart failure [21]. Although disease-specific investigative efforts have influenced the care of today’s CICU patients, research into optimal care pathways and platforms for critical care delivery in the CICU have unfortunately lagged behind.

Recognizing an increasing overlap between the contemporary CICU and other medical and surgical ICUs has helped clinicians and investigators better evaluate technologies and practices available for critically ill patients with cardiac conditions. Several studies have demonstrated that prognostic markers once reserved for general critical care populations may also have value within the CICU [22,23]. Recognizing key differences of these units has likewise been important. The increasing influence of nonsurgical cardiac interventions, including percutaneous valve replacement platforms and mechanical circulatory support (MCS) devices will undoubtedly lead to additional divergence.

As the utilization of the CICU increases and costs associated with it escalate, a more comprehensive understanding of the highest impact practices will be imperative. Halpern and Pastores reported a 200% increase in ICU costs between 1985 and 2000 [24], and went on to identify an additional 44% increase in costs between 2000 and 2005. They noted that while the total number of hospital beds had decreased in the US by over 4%, the number of critical care beds had increased by 6.5% [24]. The increasing representation of critical care in the modern medical landscape has appropriately directed research efforts towards the identification of technologies, practices, and system structures which deliver the highest value care to the sickest patients. Large databases which exist for medical ICUs have not been replicated specifically for the CICU. Therefore, much of our understanding of practice in the CICU comes from smaller, and commonly retrospective or descriptive studies.

Organizational Structure in the Contemporary CICU

Many of today’s ICUs are considered “closed” units, in which
responsibility of care for patients admitted to the intensive care setting falls to a dedicated critical care team. This structure stands in direct contrast to historical “open” units, wherein any physician may admit patients to the ICU and continue to maintain the primary role in managing them throughout their hospital course, including their intensive care. Importantly, a “closed” unit structure does not exclude involvement of a patient’s long-term providers but rather creates an environment of team-based care in which moment-to-moment care is directed by the dedicated critical care team in collaboration with the patient’s primary outpatient providers, involved specialists, and a broad group of multidisciplinary staff.

Studies of these two models within medical ICUs have generally showed better outcomes with the “closed ICU approach” [25,26]; although a more recent multicenter analysis failed to corroborate this association [27]. No studies evaluating optimal organizational structure have yet been conducted specifically in dedicated CICUs. Nonetheless, a recent survey of largely academic CICUs showed that 55% operated in a “closed” model of care. More research will be valuable to understand the impact of staffing patterns on CICU outcomes.

**Who is in Charge of the CICU?**

Defining the optimal staffing and training for today’s CICU is an important issue facing the field. Research conducted in general critical care units has demonstrated superior outcomes for patients managed by intensivists with dedicated training in the care of critically ill populations. In a systematic review, a 29% mortality reduction along with significant improvements of resource consumption was attributed to intensivist care [28]. The specialized pharmacopeia necessary for care of critically ill patients, along with the routine use of critical care procedures such as mechanical ventilation, central venous catheterization, and flexible bronchoscopy within the modern ICU create a need for clinicians with advanced critical care experience or training. Direction of care by intensivists is also believed to improve patient triage, minimize the risk for iatrogenic complications, and to reduce ICU lengths-of-stay and direct costs. Although it would seem reasonable to extrapolate these findings to CICU populations—a group of patients who have previously been shown to suffer from high rates of noncardiovascular critical illness and to require the frequent use of critical care interventions—the impact of intensivist care on outcomes in the CICU has not been directly established. At present, the prevalence of intensivist-staffing models in CICUs remains low. In a 2013 survey conducted by members of an American Heart Association Scientific Statement Writing Group, a mere 8.1% of CICU medical directors reported that intensivists served as
primary physicians for patients admitted to their units [29]. The lack of evidence directly examining an intensivist model in the CICU, combined with an acknowledgement from the general critical care community indicating a lack of complete comfort managing cardiovascular disease [30], points to a need for studies aimed at understanding optimal staffing for the CICU [31].

Critical care consultation allows for the contribution of both intensivists and cardiologists to participate in the care of CICU patients. This comanagement strategy depends upon the availability of critical care-trained physicians—specialists who are already at a significant shortage due to increasing demand and stagnating supply [32].

Telemedical consultation has also been proposed as an alternative strategy for achieving this “high-intensity staffing,” and has been successfully employed in general or mixed ICUs [33,34]. Major considerations related to costs-of-care and the lack of direct patient–physician contact, among others, require additional study before tele-ICU platforms can be widely entertained or implemented in the CICU setting.

An additional approach towards appropriate staffing of the CICU is to avail critical care training opportunities to cardiologists. Several proposed training frameworks exist by which this goal may be accomplished [31,35]. Most commonly, multiple tiers of proficiency are proposed, wherein fellows of general cardiology training programs can obtain proficiency in cardiovascular critical care delivery. A summary of one possible framework is included in Table 186.1. The optimal design and implementation such training pathways remain in evolution [31,35].

**Key Members of the CICU Team**

Nurses have been pivotal members of the CICU team since its inception in the 1960s. Equipped with defibrillators and empowered to act
autonomously to resuscitate post-MI patients, nurse-led CICU care has been associated with pronounced reductions of mortality. More recent data also suggests that nurse-to-patient ratios are significant predictors of survival [36].

In addition to nurses, the inclusion of critical care pharmacists as part of the multidisciplinary team has been associated with improved patient outcomes, reduced adverse drug events, and medication cost savings [37,38]. Respiratory therapists reduce the number of ventilator-patient days and can likewise decrease critical care costs [39,40]. Early mobility in the ICU, led by physical therapists, can also contribute to improved outcomes in several clinical domains [41]. Though all vetted in general ICU environments, there is no reason to believe that these team members should not have similar favorable impacts in the modern CICU. Additionally, palliative care expertise will likely take on increasing importance given the evolving population of today’s CICU. These specially trained clinicians can help facilitate goals-of-care discussions, address end-of-life care, and are already being called upon to support patient selection for durable MCS [42]. Potential members of the CICU team are further highlighted in Figure 186.3.

**FIGURE 186.3** Important members of the modern CICU team.

Processes and Protocols for Cardiac Critical Care
Delivery

A key mechanism through which multidisciplinary teams likely affect care is through the early implementation of proven critical care interventions. The need for data on such processes and protocols in the CICU is great. Some interventions with a strong base of evidence from research in general ICUs have already been applied in CICUs. Among these are the use of bundled care to reduce ventilator-associated pneumonia, management techniques for decreasing catheter-associated urinary tract infections, and protocols for unfractionated heparin adjustment and electrolyte replacement. There may be benefit for bundled CICU care practices in more cardiac-specific disease processes such as cardiac arrest and cardiogenic shock, but more research is needed to validate and systematize these approaches. ICU care has been compared to air traffic control, where algorithms and mechanisms for checks-and-balances are necessary to avoid serious errors. The development and validation of consistent care protocols and processes unique to the CICU must be part of the evolution of these specialized units, and comprehensive quality measures should likewise be created.
CONCLUSIONS

The modern CICU has evolved quickly and substantially from its origins as a monitoring unit specific to patients with acute MI. Now home to an increasingly diverse and complex population of patients with cardiovascular critical illness, the CICU must continue to grow responsibly. Many challenges face this maturing critical care setting. Included among these challenges are the need to determine the appropriate staffing, training, and organizational models necessary to deliver the highest quality of evidence-based care. Well-constructed responses to these challenges will only come through collaborative investigative efforts and dialogue among key stakeholders.

Advances in the prevention, diagnosis, and management of patients with acute ST-segment elevation myocardial infarction (STEMI) have led to reductions both in the incidence and in case fatality from this condition [1]. Rapid delivery of reperfusion therapy is the cornerstone of STEMI management. The development of integrated systems of STEMI care has resulted in delivery of timely reperfusion therapy to larger numbers of eligible individuals, improving patient outcomes. This chapter describes the pathophysiology of STEMI, its diagnosis, risk stratification, and management. Mechanical complications of myocardial infarction (MI) are discussed in Chapter 191. The management of cardiogenic shock, including mechanical circulatory support, is addressed in Chapters 190, 196, and 197.

**PATHOPHYSIOLOGY**

The initial pathophysiologic event leading to STEMI is usually rupture or erosion of a lipid-rich atherosclerotic plaque. The atherosclerotic plaque “vulnerable” to rupture tends to have a dense lipid-rich core and a thin protective fibrous cap and is often not associated with critical narrowing of the arterial lumen. Molecular factors that regulate synthesis and dissolution of the extracellular matrix appear to modulate integrity of the protective fibrous cap. In unstable atherosclerotic lesions, inflammatory cells accumulate at the “shoulder” region of the plaque and release proteinases that degrade extracellular matrix and weaken the fibrous cap at this critical site [2].

Following plaque rupture, platelets adhere to subendothelial collagen,
von Willebrand factor, or fibrinogen, and become activated by various local mediators such as adenosine diphosphate (ADP), collagen, and thrombin. Activated platelets undergo a conformational change and secrete the contents of their α-granules, promoting vasoconstriction and clot retraction. Activated platelets also express glycoprotein (GP) IIb/IIIa receptors in increased number and with greater binding affinity; fibrinogen-mediated cross-linking at this critical receptor leads to platelet aggregation. On the phospholipid surface of the platelet membrane, prothrombin is converted to thrombin, catalyzing the conversion of fibrinogen to fibrin [3].

The distinguishing feature of the platelet–fibrin clot in STEMI is that it completely occludes the epicardial coronary artery, leading to transmural myocardial injury, manifested by ST-segment elevation on the electrocardiogram (ECG). Despite similar initial pathophysiological features, unstable angina and non-STEMI (NSTEMI) are infrequently associated with complete occlusion of the culprit coronary artery and do not benefit from fibrinolytic therapy. Without reperfusion therapy, most patients with STEMI suffer transmural infarction and evolve Q-waves over the first few days after MI. Successful reperfusion therapy, however, may limit necrosis to the subendocardial regions and prevent development of Q-waves. The distinction between Q-wave and non-Q-wave MI can only be made retrospectively, and thus is not useful for early patient management.
DIAGNOSIS AND RISK ASSESSMENT

History and Physical Examination

The pain of acute MI is qualitatively similar to angina and is classically described as a severe pressure-type pain in the midsternum, often radiating to the left arm, neck, or jaw. Associated symptoms include dyspnea, diaphoresis, nausea, vomiting, and weakness. In the elderly and those with diabetes, pain is often atypical and may not be present at all [4]. Commonly, inferior STEMI presents with nausea and vagal symptoms rather than chest pain. Characterization of the quality of the pain may help to distinguish MI from other conditions that cause chest discomfort, such as aortic dissection, pulmonary embolism, pericarditis, and gastrointestinal (GI) disorders such as cholecystitis and peptic ulcer (Table 187.1).

CT, computed tomography; CHF, congestive heart failure; ECG, electrocardiogram; LBBB, left bundle branch block; LVH, left ventricular hypertrophy MRI, magnetic resonance imaging.

Patients with acute MI often appear pale and clammy; in many cases, they are in obvious distress. Elderly patients, in particular, may be agitated and incoherent. In contrast, patients with cardiogenic shock may be listless and confused. The objective of the initial examination should be to rapidly narrow the differential diagnosis and assess the clinical stability of the patient. A focused examination can help to differentiate ischemia from conditions such as pneumothorax, pericarditis, aortic dissection, and cholecystitis (Table 187.1). Concomitant conditions, such as valvular heart disease, peripheral vascular disease, and cerebrovascular disease, may complicate patient management and can be rapidly detected by physical examination. A brief survey for signs of congestive heart failure (HF) should be performed. Cool extremities or impaired mental status suggests decreased tissue perfusion, whereas elevated jugular venous pressure and rales suggest elevated cardiac filling pressures. Finally, the hemodynamic and mechanical complications of acute MI can often be detected by careful attention to physical findings.

An important condition that may mimic acute MI is Tako-Tsubo cardiomyopathy (also called apical ballooning syndrome or stress cardiomyopathy). This syndrome, more common among elderly women, is typically precipitated by acute emotional distress or noncardiac medical illness. The chest pain associated with anteroapical ST-segment
elevation and T-wave inversions is usually indistinguishable from an evolving anterior infarct. The diagnosis is typically made when normal coronary arteries and the distinctive anteroapical wall motion abnormality (Fig. 187.1) are seen at the time of emergent cardiac catheterization. In contrast to acute MI, cardiac enzymes usually elevate only modestly and the left ventricular (LV) functional abnormalities tend to be transient. The pathophysiology of this syndrome is considered to be caused by catecholamine-mediated myocardial stunning.

**Electrocardiogram**

Performance of the 12-lead ECG in the prehospital setting allows activation of a STEMI team prior to hospital arrival, significantly reducing time to reperfusion and leading to improved mortality [5]. The ST-segment elevation of acute MI must be distinguished from that caused by pericarditis or even the normal early repolarization variant. Ischemic ST-segment elevation typically has a convex configuration, is limited to selected ECG leads, and is often associated with reciprocal ST-segment depression (Table 187.1). Diagnostic criteria in the absence of left bundle branch block (LBBB) are based on ST-segment elevation at the J point in two contiguous leads ≥0.1 mV in all leads other than V2–V3. In V2–V3, ≥0.2 mV is required in men ≥40 years and ≥0.25 mV in men <40 years,
or ≥0.15 mV in women. Reversible ischemic ST-segment elevation is also seen with coronary vasospasm (Prinzmetal’s variant angina). Pericarditis, on the other hand, is typically associated with diffuse ST-segment elevation and depression of the PR segment (Fig. 187.2). The contour of the elevated ST segment in pericarditis and early repolarization variant is typically concave (upward sloping).

**FIGURE 187.2** Electrocardiogram changes characteristic of pericarditis. Concave (upsloping) ST-segment elevation is seen diffusely, together with PR-segment depression. Importantly, T-waves are essentially normal, another distinguishing feature from ST elevation MI.

LBBB masks ischemic ST-segment elevation. A *new* (or presumed new) LBBB in a patient with ischemic chest discomfort suggests a large anterior infarction and is an indication for reperfusion therapy. It should be emphasized that an acute STEMI leading to LBBB requires a very large ischemic territory and would not be expected to be a subtle clinical event. Old LBBB and LBBB of unknown age present a diagnostic dilemma because most of these patients do not have ongoing transmural myocardial ischemia. The Sgarbossa ECG criteria are specific but very insensitive for masked STEMI [6,7]. Among patients not meeting Sgarbossa criteria, emergent echocardiography (to look for an anterior wall motion abnormality), rapid testing of cardiac biomarkers, and even emergent cardiac catheterization should be considered (Fig. 187.3) [7].
Cardiac Biomarkers and Other Tools for Risk Assessment

Cardiac biomarkers are much more important for the initial diagnosis of NSTEMI than for STEMI. For patients with STEMI, cardiac marker measurements are used to confirm the diagnosis in patients with equivocal electrocardiographic changes and may help to gauge prognosis. Patients with an elevated cardiac troponin or B-type natriuretic peptide level prior to initiation of reperfusion therapy are at higher risk for death and HF, even after accounting for baseline variables such as infarct location and time to treatment [8,9]. The peak levels of troponin, creatine kinase (CK), or creatine kinase myocardial band (CKMB) provide a crude estimation of infarct size. It should be noted that with successful reperfusion, although the total amount of biomarker released is reduced, the peak value may actually increase, with an earlier peak and more rapid fall in biomarker levels.

Information from the patient’s clinical presentation and physical examination are also very valuable for assessing the patient’s prognosis. Evidence for HF or hemodynamic stress (Killip Classification) at the time of presentation is weighted heavily in this assessment. For example, it is
possible to use the patient’s age and vital signs at presentation to rapidly and accurately obtain a preliminary estimate of short-term survival [10]. Anterior infarct location, delays to therapy, and information regarding medical comorbidity offer additional prognostic information [11]. As such, tools such as the Thrombolysis in Myocardial Infarction (TIMI) risk score and the Global Registry of Acute Coronary Events (GRACE) model that integrate age, the physical examination, the ECG, and other clinical parameters such as serum creatinine provide very strong discrimination of short- and long-term mortality risk, and should be implemented using simple bedside calculation [11,12], handheld devices, or web-based tools [13,14] (Fig. 187.4).

**FIGURE 187.4** TIMI risk score for STEMI: a simple, bedside, clinical tool for predicting 30-day mortality. At the high end, a score of more than 5 identified 12% of patients with a mortality risk at least twofold higher than the mean for the population. In contrast, the 12% of patients with a risk score of zero had a mortality rate of less than 1%. Discriminating among the lower risk groups, nearly two-thirds of the population had risk scores of 0 to 3 with a 5.3-fold gradient in mortality over this range where smaller differences in absolute risk may have clinical impact. h/o, history of; HTN, hypertension; LBBB, left bundle branch block; STEMI, ST-segment elevation myocardial infarction; TIMI, thrombosis in myocardial infarction.

REPERFUSION THERAPY

Rapid provision of reperfusion therapy is the primary treatment objective in patients presenting with STEMI. Both primary percutaneous coronary intervention (PCI) and pharmacologic reperfusion are accepted reperfusion strategies, with primary PCI being the preferred method of reperfusion when it can be performed in a timely manner by experienced operators.

What Constitutes “Optimal” Reperfusion?

Early successful coronary reperfusion limits infarct size and improves LV dysfunction and survival. These benefits are at least in part owing to the early restoration of antegrade flow in the infarct-related artery (IRA). In a retrospective analysis of six angiographic trials of different fibrinolytic regimens, patients who achieved normal (TIMI grade 3) antegrade flow in the IRA had a 30-day mortality rate of 3.6% versus 6.6% in patients with slow (TIMI grade 2) antegrade flow and 9.5% in patients with an occluded artery (TIMI grade 0 or 1 flow) [15].

With primary PCI, normal (TIMI grade 3) epicardial blood flow is achieved in >90% of STEMI patients, in contrast to ~50% with fibrinolytic therapy. However, even among patients who achieve TIMI grade 3 flow in the IRA after reperfusion therapy, tissue-level perfusion may be inadequate. Using a number of different diagnostic tools, investigators have demonstrated that measures of tissue and microvascular perfusion provide prognostic information that is independent of TIMI flow grade [16] (Fig. 187.5). For example, Ito and colleagues, using myocardial contrast echocardiography, found impaired tissue and microvascular perfusion in approximately one-third of patients with TIMI grade 3 blood flow after primary PCI: these patients were at increased risk for the development of HF and death [17]. Microvascular dysfunction is thought to occur in the setting of MI as a result of distal embolization of microthrombi, tissue inflammation from myocyte necrosis, and arteriolar spasm caused by tissue injury.
Perhaps the most clinically relevant measure of tissue perfusion is a simple bedside assessment of the degree of resolution of ST-segment elevation on the 12-lead ECG. Greater degrees of ST-segment resolution are associated with improved IRA epicardial blood flow [18]. Furthermore, patients who have normal epicardial blood flow, but persistence of ST-segment elevation on the 12-lead ECG after reperfusion, have abnormal tissue and microvascular perfusion [19,20], which leads to poor recovery of infarct zone wall motion and higher rates of death and HF [21]. As a result, ST-segment resolution appears to integrate epicardial and myocardial (microvascular) reperfusion, and as such may actually provide a more clinically useful assessment of reperfusion than coronary angiography [22].
Regardless of the choice of reperfusion strategy, several common themes are evident. First, the benefits of reperfusion therapy are time dependent. Patients who receive fibrinolytic therapy within 1 hour from the onset of chest pain have an approximately 50% reduction in mortality, whereas those presenting more than 12 hours after onset of symptoms derive little, if any, benefit. For each hour earlier that a patient is treated with a fibrinolytic, there is an absolute 1% decrease in mortality [23]. Similarly, for primary PCI, the “door-to-balloon” time has been shown to be directly correlated with clinical benefits [24].

Although performance metrics like door-to-balloon time have catalyzed important quality improvement efforts at the institutional level after initial presentation, broader initiatives at the systemic level aimed at reducing the total ischemic time (time from initial symptom onset to perfusion) have been equally important because total ischemic time is the principal determinant of outcome. To this end, both the American College of Cardiology (ACC) and American Heart Association (AHA) have established system-wide initiatives aimed at reducing both in-hospital and prehospital system efficiency in order to reduce total ischemic time. For example, the ACC initiated the Door-to-balloon (D2B) Alliance as a quality initiative that utilizes strategies that discriminate between hospitals with short and long door-to-balloon times [25] to successfully reduce the majority of participating hospitals’ door-to-balloon times to <90 minutes [26]. In a similar manner, the AHA established the “Mission:Lifeline” program to improve health system readiness and response to STEMI, with an emphasis on Emergency Medical System activation for primary PCI. These system-wide initiatives are paramount in reducing total ischemic time and subsequently improving outcomes in patients with STEMI (Table 187.2).

**TABLE 187.2 Contemporary Components of Early STEMI Care**

- Prehospital Care
- EMS personnel perform 12-lead ECG at time of FMC
- Activation of the catheterization laboratory prior to patient arrival
- Transport directly to a PCI-capable hospital for primary PCI (if available) in <90 min
- ED
• Emergency medicine physician activates the catheterization laboratory (if patient initially presents to ED at PCI-capable hospital)
• A single call to a central page operator activates the PCI team
• Immediate transfer to PCI-capable hospital for primary PCI if FMC-to-device time <120 min if patient arrives at non-PCI-capable hospital
• Administer fibrinolytic therapy in <30 min at non-PCI-capable hospitals when anticipated FMC-to-device time at PCI capable hospital >120 min
• Cardiac catheterization laboratory
• Expectation that staff will arrive in the catheterization laboratory within 20–30 min after being paged
• Real-time data feedback is provided to emergency department and the catheterization laboratory staff

ED, Emergency Department; EMS, emergency medical services FMC, first medical contact; PCI, percutaneous coronary intervention.

Fibrinolytic Therapy

The use of fibrinolytic therapy worldwide has decreased substantially. Nevertheless, fibrinolytic therapy remains the primary approach to reperfusion therapy for some countries and in a few regions in the United States where there is no access to timely primary PCI.

Placebo-controlled trials using streptokinase, anistreplase (APSAC), and recombinant tissue plasminogen activator (tPA [Alteplase]) established a clear benefit of fibrinolytic therapy for patients with STEMI. The Fibrinolytic Therapy Trialists’ overview of all the large placebo-controlled studies reported a 2.6% absolute reduction in mortality for patients with STEMI treated within the first 12 hours after the onset of symptoms [23]. This benefit has been shown to persist through 10 years of follow-up. Highlights of differences in dosing, pharmacokinetics, recanalization rates, and cost between agents are shown in Table 187.3.

ICH, intracranial hemorrhage; tPA, Alteplase.

Several genetic alterations of tPA have led to prolonged half-life (to allow bolus administration), as well as increased fibrin specificity and resistance to endogenous inhibitors of plasminogen, such as PAI-1. Reteplase is a double-bolus agent whereas tenecteplase is administered in a single weight-adjusted bolus. Bolus administration may minimize the risk for dosing errors, decrease “door-to-needle” time, and allow for prehospital administration.

Although the bolus fibrinolytic agents have not been demonstrated in placebo-controlled trials to reduce mortality or intracranial hemorrhage (ICH), they are easier to use and have largely replaced Alteplase for this reason in the United States. Tenecteplase appears to offer a modest advantage in safety over other agents and has emerged as a preferred...
fibrinolytic agent for patients not able to receive primary PCI.

Current Guidelines for Fibrinolysis

Fibrinolytic therapy is indicated as an option for reperfusion therapy in patients presenting within 12 hours of symptom onset if they have ST-segment elevation or new LBBB and no contraindications to lytic therapy (Table 187.4), and are unable to be transferred to a PCI-capable hospital for primary PCI within 120 minutes [27]. Patients who are older than 75 years of age, those who present more than 12 to 24 hours after the onset of acute MI, and those who are hypertensive but present with high-risk MI have a less favorable balance of risk and potential benefit, but may be considered for treatment with a fibrinolytic therapy when primary PCI is not available. Dose reduction has been suggested for elderly patients being treated with tenecteplase.

<sup>a</sup>Prior recommendations have considered only a sustained blood pressure >180/110 a relative contraindication; however, even a single blood pressure greater than this threshold is associated with an increased risk for intracranial hemorrhage.

CPR, cardiopulmonary resuscitation; TIA, transient ischemic attack.

Limitations of Fibrinolytic Therapy

Current fibrinolytic regimens achieve patency (TIMI grade 2 or 3 flow) in approximately 80% of patients, but complete reperfusion (TIMI grade 3 flow) in only 50% to 60% of cases. In addition, as noted previously in this chapter, approximately one-third of patients with successful epicardial
reperfusion have inadequate myocardial and microvascular reperfusion [17]. Finally, even after successful fibrinolysis, a 10% to 20% risk of reocclusion is present. Reocclusion and reinfarction are associated with a two- to threefold increase in mortality [28].

Bleeding is the most common complication of fibrinolytic therapy. Major hemorrhage occurs in 5% to 15% of patients. ICH is the most devastating of the bleeding complications, causing death in the majority of patients affected and almost universal disability in survivors. In major clinical trials, ICH has occurred in 0.5% to 0.9% of patients, but in clinical practice, where patient selection is less rigorous, rates are higher. Patients particularly at high risk of ICH include the elderly (particularly elderly females), patients with low body weight, and those who receive excessive doses of heparin.

**Rescue Percutaneous Coronary Intervention**

Because failure of fibrinolytic therapy is associated with high rates of morbidity and mortality, “rescue” PCI is frequently performed for such patients. Because tools to diagnose failed reperfusion are only modestly effective, and clinical trials evaluating rescue PCI have enrolled very slowly, data to support rescue PCI in patients with an occluded infarct artery are limited. In the MERLIN trial, 307 patients with ECG evidence of failed reperfusion (ST-segment resolution <50% measured 60 minutes after fibrinolytic therapy) were randomized to rescue PCI or conservative therapy. Rescue PCI was performed an average of approximately 90 minutes after the qualifying ECG and was associated with a 26% reduction in the composite endpoint of death, reinfarction, stroke, HF, and revascularization at 30 days. However, mortality was not significantly reduced. The most recent study performed was the REACT trial, in which 427 patients with ECG evidence of failed fibrinolysis at 90 minutes were randomized to repeat fibrinolysis, conservative treatment, or rescue PCI. Repeat fibrinolysis did not confer a benefit in this trial, but rescue PCI reduced the primary endpoint of death, reinfarction, stroke, or severe HF at 6 months by 53%. Mortality was also reduced from 12.8% for the conservative therapy arm to 6.2% in the rescue PCI arm. We recommend urgent catheterization and PCI for all patients with persistent ST-segment elevation and ongoing chest pain 90 minutes after the administration of reperfusion therapy, unless they are at particularly low risk for complications (i.e., a young patient with an uncomplicated inferior MI). For patients who are pain free, but in whom the ST segments remain elevated, urgent catheterization should also be strongly considered, particularly if the patient has high-risk features, such as older age, anterior location of infarction, diabetes, or prior CAD. Performance of routine PCI after fibrinolytic therapy will be discussed under
Primary Percutaneous Coronary Intervention

Immediate or “primary” PCI has emerged as the clearly preferred reperfusion method for patients with STEMI. Randomized trials performed at both referral centers and experienced community hospitals have shown that primary PCI reduces the likelihood of death or MI when compared to fibrinolytic therapy [29]. Moreover, rates of major bleeding and stroke are also significantly lower with primary PCI than with fibrinolytic therapy (Fig. 187.6). The relative benefits of primary PCI are greatest in patients at highest risk, including those with cardiogenic shock, right ventricular infarction, large anterior MI, and increased age (partly owing to an increased ICH rate with fibrinolytic therapy). However, as with fibrinolytic therapy, rapid time to treatment is paramount to success [24]. In addition, although operator and institutional experience are critical to realize the full benefit of primary PCI, excellent results with primary PCI have been demonstrated in well-trained community hospitals without on-site cardiac surgery [30].

Current ACC/AHA guidelines recommend primary PCI of the infarct artery over fibrinolytic therapy when time-to-treatment delays are short and the patient presents to a high-volume, well-equipped center with experienced interventional cardiologists (ideal first medical contact (FMC)-to-device time <90 minutes at PCI-capable hospitals). When the FMC-to-device time is expected to be longer than 120 minutes, fibrinolysis is generally preferred for patients presenting within 12 hours of symptom onset unless contraindications are present (Fig. 187.7) [27].
FIGURE 187.6 Short-term (4- to 6-week) outcomes from a meta-analysis of 23 randomized controlled trials comparing fibrinolytic therapy with primary percutaneous coronary intervention. (Adapted from Keeley EC, Boura JA, Grines CL: Primary angioplasty versus intravenous thrombolytic therapy for acute myocardial infarction: a quantitative review of 23 randomised trials. Lancet 361(9351):13–20, 2003.)

FIGURE 187.7 An algorithm for triage and
transfer for primary percutaneous coronary intervention among patients with ST elevation myocardial infarction.

Advances in PCI technology have been rapidly translated from elective to emergent PCI. Compared with primary percutaneous transluminal coronary angioplasty PTCA, primary stenting is associated with similar rates of death and reinfarction but lower subsequent target vessel revascularization rates [31,32]. Initial fears about stent thrombosis when drug-eluting stents (DES) were placed in the setting of STEMI have not been realized, and the advantages of DES over bare metal stents (BMS) with regard to in-stent restenosis and target vessel revascularization extend to patients with STEMI [33,34]. Nonetheless, current ACC/AHA guidelines recommend that BMS be used for patients in whom there is uncertainty regarding their ability to comply with prolonged dual-antiplatelet therapy (DAPT), whether related to bleeding risk or adherence concerns. However, recent data comparing BMS and newer generation everolimus-eluting stents (EES) show that EES have lower rates of stent thrombosis [35]. In addition, there is a growing body of evidence suggesting that shorter duration DAPT (<12 months) following DES placement is associated with fewer bleeding complications and acceptable rates of stent thrombosis [36]. Therefore, newer generation EES utilizing everolimus are generally preferred over BMS, even if prolonged DAPT use is uncertain. BMS may still be an acceptable option when these stents are not available, or if treatment with DAPT for at least 3 months is not possible.

Arterial Access

Vascular access bleeding is the most common complication after primary PCI for STEMI. One strategy that appears to decrease bleeding complications is the use of radial artery access. Among the 1,958 patients with STEMI in the Radial Versus Femoral Access for Coronary Angiography and Intervention in Patients with Acute Coronary Syndromes (RIVAL) trial [37], randomization to radial access was associated with a 40% reduction in the composite primary outcome of death, MI, stroke and non-coronary artery bypass graft (ČABG)-related bleeding when compared with femoral access (heart rate [HR] 0.60, 95% confidence interval [CI] 0.38 to 0.94, \( p = 0.026 \)). In a post hoc analysis of STEMI patients included in the RIVAL trial, there also appeared to be
reduction in all-cause mortality with radial compared to femoral artery access (1.3% vs. 3.2%; HR 0.39; p = 0.006), a benefit not observed among the NSTEMI subgroup [38]. The Minimizing Adverse Hemorrhagic Events by TRansradial Access Site and Systemic Implementation of angioX (MATRIX) trial [39] was a randomized superiority trial comparing radial versus femoral access in 8,404 patients with acute coronary syndrome (48% with STEMI). Compared with femoral artery access, radial access was associated with less death, MI, and stroke (8.8% vs. 10.3%, relative risk (RR) 0.85; 95% CI 0.74 to 0.99; p = 0.03). All-cause mortality was also reduced (1.6% vs. 2.2%; RR 0.72; 95% CI 0.53 to 0.99; p = 0.045), consistent with results from the RIVAL trial. Based on these data, radial artery access is becoming the preferred route of vascular access for patients with STEMI in many parts of the world, with increasing use in the United States. Data from 593,094 procedures in the National Cardiovascular Data Registry (NCDR) showed that when compared to femoral artery access, radial artery access was associated with similar procedural success (odds ratio [OR] 1.02, 95% CI 0.93 to 1.12) but significantly lower bleeding complications (OR 0.42, 95% CI 0.31 to 0.56) [40].

Multivessel CAD

Approximately 50% of patients presenting with STEMI have multivessel disease [41,42]. Percutaneous treatment options for patients with STEMI and multivessel CAD include culprit-vessel-only PCI, multivessel PCI performed at the time as primary PCI, or immediate culprit PCI with “staged” PCI of nonculprit vessels at a later time during the index hospitalization. Previous clinical practice guidelines recommended against PCI of a noninfarct artery at the time of primary PCI in hemodynamically stable patients (class III), based exclusively on observational data. However, recent small randomized controlled trials have led to a shift in practice recommendations. In the Preventative Angioplasty in Acute Myocardial Infarction trial that included 465 patients with STEMI and multivessel CAD, multivessel primary PCI was associated with a significant decrease in the composite primary outcome of cardiac death, nonfatal MI, or refractory angina when compared with culprit-artery-only PCI (9% vs. 22%, HR 0.35, 95% CI 0.21 to 0.58; p < 0.001), with directionally concordant changes in each element of the primary endpoint [43]. In the Complete Versus Culprit-Lesion Only Primary PCI trial, 296 patients with STEMI were randomized to culprit-only versus multivessel PCI, performed either during the index procedure or during the index hospitalization (72% performed during the index procedure). A significant reduction in the composite primary outcome of death, reinfarction, HF, and ischemic-driven revascularization was seen
among patients randomized to multivessel PCI versus culprit-only PCI (10% vs. 21%, HR 0.49, 95% CI 0.24 to 0.84, \( p = 0.009 \)) [44]. Based on these trials and data from other similar studies [45,46], the prior Class III (harm) recommendation was upgraded to a Class IIb recommendation with regard to the consideration of multivessel PCI in patients presenting with STEMI, either at the time of primary PCI or as a planned, staged procedure [47].

**Thrombus Aspiration**

Because of the large thrombus burden in STEMI, distal embolization at the time of PCI is common and may cause additional tissue and microvascular injury. Strategies to prevent distal embolization using embolic protection devices, which are commonly used when PCI is performed in saphenous vein grafts, cause delays in reperfusion and do not appear to improve outcomes when STEMI is caused by native vessel obstruction [48]. An alternative approach to decrease distal embolization is manual aspiration thrombectomy, which was previously supported by a class IIa recommendation [27], based on favorable results from a small trial [49]. However, several large and recent multicenter trials have prompted a shift in guideline recommendations. In the Thrombus Aspiration During ST-Segment Elevation Myocardial Infarction trial of 7,244 patients with STEMI, aspiration thrombectomy prior to primary PCI was not associated with improved short-term differences in death (2.8% vs. 3.0%, \( p = 0.63 \)), reinfarction (0.5% vs. 0.9%, \( p = 0.09 \)), stent thrombosis (0.2% vs. 0.5%, \( p = 0.06 \)), or target vessel revascularization (1.8% vs. 2.2%, \( p = 0.27 \)), when compared with primary PCI only [50]; these results were similar at 1 year follow-up [51]. In the Trial of Routine Aspiration Thrombectomy With PCI Versus PCI Alone in Patients with STEMI (TOTAL) trial, 10,732 patients with STEMI were randomized to either aspiration thrombectomy prior to primary PCI or primary PCI only. There were no significant differences between the two groups at 6 months with regard to the composite of cardiovascular death, recurrent MI, cardiogenic shock, or New York Heart Association Class IV HF (6.9% vs. 7.0%, \( p = 0.86 \)) [52]. Collectively, these data have led to routine aspiration thrombectomy before primary PCI being downgraded from a class IIa recommendation to a class III recommendation [47]. It is unclear whether selective use or “bailout” thrombectomy in patients with large thrombus burden is beneficial (class IIb).

---

**Transfer to Primary Percutaneous Coronary**
Intervention

Although primary PCI is the preferred reperfusion option for most patients who present to dedicated centers that can perform interventional procedures quickly and expertly, many patients with STEMI present to centers without primary PCI readily available. In such cases, a decision must be made as to whether immediate pharmacologic reperfusion therapy or transfer for primary PCI (if possible) is the best alternative. For patients transported to a non-PCI-capable hospital in whom a rapid transfer is possible (time from FMC-to-device system time <120 minutes or less), transfer for primary PCI is preferable (Fig. 187.7) [28]. Unfortunately, data from the AHA Mission:Lifeline Program between 2008 and 2012 showed 35% of STEMI patients transferred for primary PCI failed to achieve FMC-to-device time of <120 minutes [53].

Independent predictors of delay in this population included patient comorbidities (cardiogenic shock, cardiac arrest), process variables (prolonged door-in door-out time, rural hospital locations), and lower PCI hospital annual STEMI volumes. These data reemphasize the importance of ongoing efforts to improve access to rapid care in patients with STEMI. For patients with contraindications to fibrinolytic therapy, evidence of failed fibrinolytic therapy, cardiogenic shock, presentation more than 12 hours after symptom onset, or transfer to a center that can perform emergent PCI is indicated, even if delay times are longer [27].

Several studies have compared various strategies of routine transfer for primary PCI of patients eligible for fibrinolytic therapy versus immediate fibrinolysis with or without transfer. Although these studies have reported a lower incidence of adverse cardiac events among those randomized to transfer for primary PCI [54,55], generalizability of the results has been questioned because the very rapid transfer times in these studies are significantly shorter than those typically occur in the United States [56] and the rates of referral for rescue PCI were unusually low in these trials.

Subsequent analyses have helped to define the influence of symptom duration and transfer-related time delay on the benefits of transfer for primary PCI. For example, among the 850 patients enrolled in the PRAGUE-2 study, there was a significant and quantitatively large reduction in mortality (6.0% vs. 15.3%; \( p < 0.02 \)) among those who were randomized more than 3 hours after symptom onset. In contrast, there was no reduction in mortality among patients presenting within 3 hours [57]. Similar findings were observed in the Comparison of Angioplasty and Prehospital Thrombolysis in Acute Myocardial Infarction (CAPTIM) trial in which the control arm received prehospital fibrinolytic [58]. A meta-analysis of randomized studies has suggested that if the delay between immediate administration of a fibrinolytic and initiation of PCI
is more than 1 hour, the pharmacological therapy becomes favored with respect to survival [59]. These data form the basis of the recommendation in the AHA/ACC guidelines that fibrinolysis, in the absence of contraindications, should be used in patients with STEMI and ischemic symptom onset <12 hours when it is anticipated that primary PCI cannot be performed within 120 minutes of FMC [27].

Pharmacoinvasive Strategies

In light of the deleterious impact of delays to primary PCI on myocardial salvage, an approach in which reperfusion is initiated with a pharmacological regimen and followed by angiography and PCI is potentially attractive, particularly for patients being transferred for primary PCI who are anticipated to have longer FMC device times. In the modern era, it is clear that PCI can be performed effectively and safely early after fibrinolytic therapy [60]. In addition, it is well known that patients who arrive in the catheterization laboratory with a patent IRA prior to “primary” PCI, owing to either spontaneous lysis or pharmacologic reperfusion, have an extraordinarily low risk of mortality [61].

The term “facilitated” PCI has been coined to signify the administration of a pharmacological reperfusion regimen en route to the cardiac catheterization laboratory for a planned “primary” PCI. A number of different pharmacological pretreatment regimens have been proposed, including fibrinolytic agents alone (at full or reduced dose), combinations of GP IIb/IIIa inhibitors and reduced-dose fibrinolytics, or GP IIb/IIIa inhibitors alone. Clinical trial results regarding facilitated PCI using regimens that contain a fibrinolytic have been disappointing: although surrogate measures of early reperfusion are enhanced, no favorable efficacy outcomes have been observed and bleeding rates are clearly increased [62,63]. Moreover, the usefulness of administration of a GP IIb/IIIa inhibitor alone prior to the arrival in the catheterization laboratory is uncertain [27,63].

An alternative pharmacoinvasive strategy that may be logistically attractive for patients presenting to non-PCI centers is to perform initial pharmacologic reperfusion therapy followed by transfer for routine nonemergent coronary angiography and revascularization if needed. This pathway has shown favorable results in several relatively small studies [64–66] and the larger Trial of Routine Angioplasty and Stenting after Fibrinolysis to Enhance Reperfusion in Acute Myocardial Infarction (TRANSFER-AMI) trial [67]. In TRANSFER-AMI, 1,059 high-risk patients with STEMI presenting to hospitals without PCI capability received pharmacological reperfusion with a regimen that contained tenecteplase and were randomized to standard treatment on site or to
immediate transfer and PCI within 6 hours after fibrinolysis. Interestingly, most patients in the standard treatment arm underwent coronary angiography, but this was performed approximately 1 day later than in the transfer arm. The primary endpoint of death, MI, recurrent ischemia, HF, or cardiogenic shock within 30 days was reduced from 17.2% in the standard treatment arm to 11.0% in the early PCI arm (HR 0.64; \( p = 0.004 \)). For patients who present to hospitals without PCI capability and in whom the door-to-balloon time is expected to be longer than 90 minutes, these data support a strategy of “drip and ship,” in which standard pharmacological reperfusion therapy is administered and the patient transferred for subsequent catheterization and PCI. The timing of the catheterization and PCI remains controversial. Data from studies of facilitated PCI suggest that very early PCI (i.e., within 2 hours) is not helpful and may be harmful. However, the accumulated data described previously suggest favorable outcomes if the PCI is performed between 3 and 24 hours after successful fibrinolytic therapy. Current ACC/AHA guidelines provide a class IIa recommendation for coronary angiography in STEMI patients treated with fibrinolytic therapy, either as soon as logistically possible (in the case of suspected failed reperfusion) or between 3 and 24 hours after successful reperfusion with fibrinolytic therapy [27].

**STEMI and Out-of-Hospital Cardiac Arrest**

Sudden cardiac death caused by cardiac arrest accounts for the majority of coronary heart disease deaths annually in the United States [68]. Although only 23% of out-of-hospital cardiac arrest cases have a shockable initial rhythm, the majority of neurologically intact survivors arise from this subgroup [28]. Two randomized controlled trials showed improved rates of neurologically intact survival of comatose patients presenting with out-of-hospital ventricular fibrillation (VF) or pulseless ventricular tachycardia (VT), who are cooled to between 32°C and 34°C for 12 and 24 hours on presentation. However, the ideal temperature target to best improve clinical outcomes remains unclear. A randomized control trial comparing targeted temperature management to 33°C versus 36°C for patients surviving out-of-hospital cardiac arrest observed no significant differences in death or poor neurologic function at 6 months (54% vs. 52%, \( p = 0.78 \)) [69], suggesting that perhaps preventing hyperthermia may be a more important treatment goal than achieving hypothermia. Current professional society recommendations advise that patients with STEMI and out-of-hospital cardiac arrest should receive
targeted temperature management before or at the time of cardiac catheterization [28]. Observational studies indicate that reasonable clinical outcomes can be expected for comatose patients after cardiac arrest who have diagnostic ST-elevation and undergo primary PCI. Neither the presenting cardiac arrest nor initiation of targeted temperature management should delay or deter primary PCI in patients with STEMI.
ADJUNCTIVE ANTIPLATELET AND ANTITHROMBOTIC THERAPY

Aspirin and P2Y<sub>12</sub> Inhibitors

For patients with STEMI, aspirin decreases reocclusion and reinfarction rates by nearly 50% and mortality by approximately 25% [70]. The benefits of aspirin are comparable to those of fibrinolytic therapy, and when used together, aspirin and fibrinolytic therapy provide additive benefits [71]. Aspirin should be initiated at an oral dose of 162 to 325 mg (preferably chewed) at the time the patient is first encountered by medical personnel in the field or emergency department. Following MI, lifelong therapy with aspirin is indicated to prevent recurrent cardiac events. Efficacy appears to be similar at all doses greater than 75 mg, whereas bleeding risk clearly increases with higher aspirin dose. However, despite increased bleeding risk, evidence from the NCDR from 2007 to 2011 shows the majority of acute coronary syndrome patients in the United States are discharged on high-dose aspirin [72]. Following the initial higher dose (162 to 325 mg) administered acutely in STEMI, the authors strongly favor an 81-mg dose of aspirin over higher dosages for long-term secondary prevention for all patients with STEMI [27,73].

In addition to aspirin, a second antiplatelet agent should be added for the acute management and secondary prevention in patients with STEMI. In particular, a series of trials established the benefits of inhibiting the binding of ADP to the P2Y<sub>12</sub> receptor on the platelet surface, thereby decreasing platelet activation and aggregation. Clopidogrel is a thienopyridine derivative that is a P2Y<sub>12</sub> antagonist. The Clopidogrel as Adjunctive Reperfusion Therapy-Thrombolysis in Myocardial Infarction 28 (CLARITY-TIMI 28) trial compared clopidogrel (300-mg loading dose followed by 75 mg per day) with placebo in 3,491 patients with STEMI who were treated with standard pharmacological reperfusion including fibrinolytic therapy, aspirin, and heparin. The primary composite endpoint of death, MI, or an occluded IRA assessed at the time of protocol-mandated angiography (average 3 to 4 days) was reduced from 21.7% in the placebo arm to 15.0% in the clopidogrel arm (p < 0.001). At 30 days, the clinical composite of death, MI, or urgent revascularization was reduced by 20% (p = 0.03) [74]. The much larger Clopidogrel and Metoprolol in Myocardial Infarction Trial (COMMIT) trial was performed in more than 45,000 patients in China and was designed to evaluate the impact of adjunctive clopidogrel (administered at 75 mg per day without
a loading dose) on death and major clinical events. Clopidogrel reduced death, reinfarction, or stroke by 9% and death alone by 7%, both of which were statistically significant [75]. Based on the results of these two trials, clopidogrel should now routinely be added to standard fibrinolytic regimens in patients inpatients younger than 75 years [27].

For patients undergoing primary PCI, similarly, an oral P2Y_{12} receptor antagonist should be administered in addition to aspirin: a loading dose followed by a minimum of 12 months of maintenance therapy is recommended for patients with STEMI receiving a stent (BMS or DES) [27]. Presently available alternatives include clopidogrel, prasugrel, and ticagrelor.

If clopidogrel is used, a loading dose of 600 mg is preferred and should be given as early as possible before or at the time of PCI [27]. In the CURRENT/OASIS 7 trial, which compared high-dose (600-mg loading dose, 150 mg per day for 7 days, and then 75 mg per day) with standard-dose (300-mg loading dose and then 75 mg per day) clopidogrel, the higher dose clopidogrel strategy was associated with a lower rate of cardiovascular death, MI, or stroke at 30 days and a lower rate of stent thrombosis (4.0% vs. 2.8%) among the subgroup with STEMI (n = 6,346). The higher dose clopidogrel regimen was also associated with a higher rate of major bleeding (1.1% vs. 1.6%; p = 0.006) [76].

Prasugrel is a second-generation thienopyridine that is more rapidly acting, more potent, and associated with less response variability than clopidogrel. The Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel-Thrombolysis in Myocardial Infarction (TRITON-TIMI) 38 trial [77] enrolled 13,608 patients with acute coronary syndrome who were scheduled to undergo PCI. Patients were randomized to prasugrel (60-mg loading dose and then 10 mg per day) or clopidogrel (300-mg loading dose and then 75 mg per day): both the drugs were initiated at the time of PCI with no pretreatment given. In the subgroup of patients with STEMI (n = 3,534), the primary efficacy endpoint of CV death, MI, and stroke at a median of 14.5 months was reduced from 12.4% in the clopidogrel arm to 10.0% in the prasugrel arm (HR 0.79; p = 0.02; Table 187.5). Stent thrombosis occurred in 2.8% STEMI patients randomized to clopidogrel versus 1.6% randomized to prasugrel (p = 0.008). Importantly, in the STEMI subgroup, no significant differences were noted in non-CABG bleeding between treatment arms. Prasugrel was associated with net harm among patients with prior stroke or transient ischemic attack (largely caused by an excess in ICH) and is contraindicated in such patients. In addition, there were two important subgroups in whom prasugrel was associated with excess bleeding that nullified clinical benefit, including patients >75 years of age and those <60 kg [77].
Ticagrelor is a direct acting and reversible non-thienopyridine oral P2Y$_{12}$ antagonist. This agent provides more rapid onset (and offset) of action and a more potent and predictable antiplatelet response than clopidogrel. It does not require activation by the cytochrome p450 system. In the Study of Platelet Inhibition and Patient Outcomes (PLATO) trial [78], ticagrelor (180-mg loading dose, 90 mg twice daily) was compared with clopidogrel (300- to 600-mg loading dose, 75 mg daily) in 18,624 patients with ACS, 38% of whom had STEMI. At the end of the 12-month follow-up period, the primary endpoint of CV death, MI, and stroke occurred in 11.7% of subjects in the clopidogrel arm versus 9.8% in the ticagrelor arm (HR 0.84; 95% CI 0.77 to 0.92; $p < 0.001$). The risk reduction was similar in the STEMI subgroup (HR 0.84; 95% CI 0.72 to 0.98; Table 187.5). Similar to the findings in the

Note that endpoint assessment was at 15 months in TRITON-TIMI 38 and 12 months in PLATO.

$^a$The stent thrombosis and bleeding results from PLATO are from the entire study because the specific data for STEMI have not yet been reported.

$^b$TIMI major bleeding (non-CABG) was the primary bleeding endpoint in TRITON-TIMI 38 and was an additional bleeding endpoint in PLATO.

STEMI, ST-segment elevation myocardial infarction; MI, myocardial infarction.
CURRENT/OASIS 7 and TRITON-TIMI 38 trials, stent thrombosis was reduced significantly with the more potent oral antiplatelet regimen. Also consistent with prior studies, ticagrelor increased non-CABG major bleeding (4.5% vs. 3.8%, \( p = 0.03 \)) [78]. Notably, in the PLATO trial, treatment with ticagrelor resulted in a significant 21% relative risk reduction in vascular mortality and a 22% reduction in total mortality (5.9% vs. 4.5%; \( p < 0.001 \)). This mortality reduction was unique to PLATO among the trials of P2Y\(_{12}\) antagonists.

Ticagrelor has side effects that are likely mediated by increases in circulating adenosine. Dyspnea occurs in 10% to 15% of patients early after treatment initiation, is not associated with HF, and is usually transient. Ventricular pauses may also be triggered by ticagrelor early after treatment initiation, but these pauses also decrease in frequency over time, are rarely symptomatic, and have not required an excess of clinical intervention. Because of these side effects, the clinician should be aware of a history of reactive airway disease or significant ECG conduction abnormalities when considering ticagrelor.

The onset of action of oral P2Y\(_{12}\) inhibitors may be delayed among patients with STEMI; possibly owing to reduced gut perfusion that is common early after presentation. Morphine administration also appears to reduce absorption of P2Y\(_{12}\) inhibitors and contribute to delayed onset of action [79–81]. Cangrelor is a novel intravenous, fast-acting, and reversible P2Y\(_{12}\) inhibitor that may offer an alternative strategy for patients to achieve rapid P2Y\(_{12}\) inhibition. However, the available data are limited to comparisons with clopidogrel and do not provide strong support for a favorable risk/benefit profile of this drug in STEMI [82]. Given the high cost, at the present time, we generally limit cangrelor use to patients unable to take oral P2Y\(_{12}\) inhibitors.

**GP IIb/IIIa Inhibitors**

Although use of GP IIb/IIIa inhibitors in elective PCI has been decreasing, these agents remain useful adjuncts to primary PCI for patients with STEMI when heparin is the anticoagulant used. In a meta-analysis involving 3,266 patients enrolled in four randomized trials comparing abciximab with placebo, patients receiving abciximab had a 46% reduction in 30-day death, reinfarction, and urgent target vessel revascularization compared to those who received placebo [83]. Fewer data are available for the other GP IIb/IIIa inhibitors (tirofiban and eptifibatide) in the primary PCI setting. Moreover, data are very limited in the current era of more potent and rapidly acting P2Y\(_{12}\) inhibitors. Current ACC/AHA guidelines recommend selective use of GP IIb/IIIa
inhibitors at the time of primary PCI (class IIa recommendation) for
selected patients who are receiving unfractionated heparin [27].

Antithrombin Therapies in Patients Receiving Fibrinolytic Therapy

The AHA/ACC guidelines recommend administration of an anticoagulant
(unfractionated heparin (UFH), enoxaparin, or fondaparinux) as
adjunctive therapy in all patients receiving pharmacologic reperfusion
therapy with the fibrin-specific agents alteplase, reteplase, or
tenecteplase. For UFH, recommended dosing is a 60 U per kg bolus
(maximum bolus of 4,000 U) plus an initial infusion of 12 U/kg/h (with a
maximum initial infusion rate of 1,000 U per hour) for up to 48 hours.
Low molecular weight heparins (LMWHs) represent an attractive
alternative to UFH for patients receiving fibrinolytic therapy. In the
Enoxaparin and Thrombolysis Reperfusion for Acute Myocardial
Infarction Treatment - Thrombolysis in Myocardial Infarction
(ExTRACT-TIMI) 25 trial [84], which randomized 20,506 patients
treated with fibrinolytic therapy to intravenous UFH for 48 hours or
enoxaparin through hospital discharge, the primary endpoint of death or
reinfarction was reduced from 12.0% in the UFH arm to 9.9% in the
enoxaparin arm (RR 0.83; p < 0.001). Major bleeding occurred in 1.4% of
UFH-treated patients versus 2.1% of those treated with enoxaparin (p <
0.001), but there was no significant difference in ICH, and the net clinical
benefit (death/MI/major bleeding) favored enoxaparin. The direct
antithrombin agents have also been extensively studied as adjuncts to
fibrinolytic therapy but appear to offer no significant advantage over
UFH when given with any of the currently available fibrinolytic agents
[85–87]. Thus, of the currently available antithrombin agents, LMWH
administered for the duration of the hospitalization (up to 8 days, or until
PCI) has been shown to be superior to short-term use of UFH and
represents the most attractive strategy for patients managed with a
fibrinolytic.

Antithrombin Therapy as an Adjunct to Primary PCI

Intravenous UFH, with or without a GP IIb/IIIa receptor antagonist, and
titrated to an appropriate activated clotting time, has been a cornerstone
adjunctive therapy for patients with STEMI undergoing primary PCI.
Multiple studies have compared bivalirudin, a direct-acting
antithrombin, as alternative to UFH in this setting. In the Harmonizing
Outcomes with Revascularization and Stents in Acute Myocardial
Infarction (HORIZONS-AMI) trial [88], 3,602 patients undergoing
primary PCI for STEMI were randomized to standard care with heparin
plus a GP IIb/IIIa inhibitor or to bivalirudin alone. The primary outcome, which was a composite of efficacy and safety endpoints at 30 days, was significantly lower in the bivalirudin versus heparin/GP IIb/IIIa inhibitor arm (9.2% vs. 12.1%; RR 0.76; \( p = 0.005 \)). This was mediated by lower rate of major bleeding with bivalirudin (4.9% vs. 8.3%; RR 0.60; \( p < 0.001 \)) and similar rates of the ischemic outcomes. Total mortality (2.1% vs. 3.1%; \( p = 0.05 \)) and cardiac mortality (1.8% vs. 2.9%; \( p = 0.03 \)) trended lower in the bivalirudin arm. An issue of concern was an increased risk of stent thrombosis within the first 24 hours in the bivalirudin group. Subsequent studies confirmed lower rates of bleeding but higher rates of stent thrombosis with bivalirudin compared with UFH plus GP IIb/IIIa inhibitor therapy and did not substantiate the reduction in all-cause mortality [89].

An important limitation of these trials is that they all compared bivalirudin versus UFH plus a GP IIb/IIIa inhibitor, which may have contributed to the higher risk of bleeding with UFH rather than to UFH alone. This limitation is of particular relevance, given the declining use of GP IIb/IIIa inhibitors in contemporary STEMI treatment. The Unfractionated heparin versus bivalirudin in primary percutaneous coronary intervention (HEAT-PPCI) trial randomized 1,829 patients undergoing primary PCI for STEMI to either heparin or bivalirudin [90]. Importantly, the use of GP IIb/IIIa inhibitor use was similar in each arm (13% and 15%, respectively), and over 90% of patients were treated with either prasugrel or ticagrelor. Patients randomized to bivalirudin were more likely to have stent thrombosis (3.4% vs. 0.9%, RR 3.91, 95% CI 1.61 to 9.52), as well as a numerically greater (but not statistically significant) trend in the composite primary outcome of all-cause mortality, stroke, reinfarction, or revascularization (8.7% vs. 5.7%, RR 1.52, 95% CI 0.9 to 2.13; Fig. 187.8). Interestingly, there was no significant difference in bleeding between the two treatment groups, likely related to lower dosages of heparin used compared with prior studies, balanced and low rates of GP IIb/IIIa inhibitor use in both arms, as well as significant utilization of radial artery access (~80%).
Results from the HEAT-PPCI Trial. Compared with bivalirudin, heparin reduced the incidence of major adverse ischemic events in the setting of primary percutaneous coronary intervention, with no increase in bleeding complications.

These findings highlight the conflicting data regarding the optimal antithrombin regimen for patients with STEMI. A meta-analysis
including 16 randomized control trials comparing bivalirudin with heparin found that bivalirudin use was associated with increased risk of MI and stent thrombosis, but a decreased risk of bleeding, with the magnitude of the bleeding reduction dependent on concomitant GP IIb/IIIa use [91]. However, comparisons of trials are difficult owing to varying dosages of heparin and GP II/IIIa inhibitor use, as well as radial versus femoral access use. In our opinion, given its markedly lower cost, UFH should be the anticoagulant of choice for primary PCI for STEMI, with bivalirudin restricted to patients at high risk for bleeding in whom radial access is not utilized.

Warfarin/Oral Anticoagulation

In the era of DAPT, the use of warfarin, either alone or in combination with DAPT, must be weighed carefully. The availability of P2Y₁₂ inhibitors has virtually eliminated the past reliance on warfarin for aspirin-allergic patients. However, because warfarin is superior to aspirin in preventing systemic emboli in patient with atrial fibrillation, and reduces systemic emboli in patients with documented LV dysfunction following MI, there are some circumstances warranting consideration of warfarin use, particularly when the risk of thromboembolism exceeds the risk of bleeding. Current ACC/AHA guidelines support warfarin use in addition to DAPT for patients who have mechanical heart valves, recent venous thromboembolism, hypercoagulable disorders, or atrial fibrillation with an elevated stroke risk (class I). Warfarin use is also reasonable for STEMI patients with asymptomatic LV mural thrombi (class IIa), and perhaps for some STEMI patients with anterior apical akinesis (class IIb) [27]. For patients with or at risk for LV thrombus, the duration of warfarin use can be limited to 3 months. It should be noted that the newer direct oral anticoagulants have not been evaluated in this clinical context, so their use cannot be recommended.

An increasingly challenging scenario relates to the combination of aspirin, a P2Y₁₂ inhibitor, and warfarin. “Triple therapy” is associated with substantially increased risks for bleeding. In a registry analysis of 480 patients, triple therapy was associated with a 50% increase in bleeding compared to DAPT alone [92]. It may be expected that risks will be even higher with combinations that include the newer and more potent antiplatelet agents such as prasugrel and ticagrelor. As such, we recommend attempting to avoid altogether or to minimize the duration of triple therapy. Consideration should be given to using BMS instead of DES, which would allow the duration of clopidogrel to be reduced to 1 month. For patients who require triple therapy, the international normalized ratio (INR) should be maintained at the lowest end of the therapeutic range (2.0 to 2.5), aspirin dose should be 81 mg, and GI
prophylaxis with a proton pump inhibitor (other than omeprazole if possible) should be considered. For patients with atrial fibrillation, a reevaluation of the risks of bleeding and stroke (using a tool such as the CHADS$_2$-VASCscore) should be performed and the threshold to initiate or continue warfarin may be higher among patients on aspirin and P2Y$_{12}$ inhibitor [93].

Another strategy being evaluated is withdrawal of the aspirin component of triple therapy. In the What is the Optimal antiplatElet and Anticoagulant Therapy in Patients With Oral Anticoagulation and Coronary StenTing (WOEST) trial [94], 573 patients on oral anticoagulation and undergoing PCI were randomized to warfarin + clopidogrel alone versus warfarin + clopidogrel plus aspirin (triple therapy). Patients treated with warfarin + clopidogrel had significantly fewer bleeding episodes when compared with those patients treated with triple therapy (HR 0.36, 95% CI 0.26 to 0.50; \( p < 0.0001 \)). Surprisingly, the group randomized to withhold aspirin also had markedly lower rates of all-cause mortality than the triple therapy group (2.5% vs. 6.3%, \( p = 0.03 \)). However, owing to the small size of the study, and because most patients enrolled did not have ACS, it is difficult to extrapolate these results to patients with STEMI. Ongoing research efforts continue to search for the optimal risk/benefit profile in this complex patient population.
ANTI-ISCHEMIC THERAPY

ß-Blockers

ß-blockers were among the first therapeutic interventions used to limit the size of acute MI. Previous trials that excluded patients with HF, hypotension, or bradycardia demonstrated that very early administration of a ß-blocker decreases infarct size and prevents recurrent MI and death [95]. The fact that ß-blockers were particularly effective in reducing sudden death and reducing mortality among patients with complex ventricular ectopy at baseline suggests that ß-blockers exert much of their beneficial effect by reducing the frequency and severity of arrhythmias [96]. In addition, they appear to significantly decrease the risk of cardiac rupture. Data from the COMMIT trial in more than 45,000 patients, however, failed to demonstrate benefit from a strategy of immediate intravenous metoprolol followed by 200 mg metoprolol daily on in-hospital outcomes, including death and MI. Although early ß blockade reduced the risks of reinfarction and VF compared to placebo, this was counterbalanced by an increased risk of cardiogenic shock during the first few days after admission [97]. Post hoc analyses indicate that this increased risk was predominantly among patients with indicators of or risk factors for hemodynamic compromise. In addition, the outcome may have been influenced by the high dose of metoprolol used in this study. ACC/AHA guidelines now recommended that ß-blockers be initiated orally, within the first 24 hours, once it has been determined that the hemodynamic status is stable and there is no evidence of HF. Parenteral ß-blockers should be used only if there is a clear indication such as ongoing chest pain or an atrial tachyarrhythmia with normal or elevated blood pressure [27].

When given long-term following MI, ß-blockers significantly reduce the incidence of nonfatal reinfarction and mortality, an effect that extends to most members of this class of agents [96]. The Carvedilol Post-Infarct Survival Control in LV Dysfunction (CAPRICORN) trial examined the incremental effects of ß blockade to angiotensin-converting enzyme (ACE) inhibition in post-MI in patients with LV dysfunction but no clinical HF. Over a mean follow-up of 1.3 years, the composite of death and MI was reduced from 20% in the placebo arm to 14% in the carvedilol arm, a 29% relative reduction. On the basis of robust clinical data and a very favorable cost-to-benefit ratio, long-term oral ß blockage should be continued for at least 3 years in patients without HF following MI [98].
Renin-Angiotensin-Aldosterone System Inhibitors

ACE inhibitors are routinely used following STEMI to prevent adverse LV chamber remodeling, a gradual process by which the left ventricle assumes a more globular shape and dilates; remodeling is associated with an increased risk for HF and death. A large overview of almost 100,000 patients found a 7% reduction of 30-day mortality when ACE inhibitors were given to all patients with acute MI, with most of the benefit observed in the first week. The benefit was greatest in high-risk groups, such as those in Killip class II or III, those with LV dysfunction, and those with an anterior MI [99]. In addition to preventing remodeling and HF, ACE inhibitors prevent recurrent ischemic events after MI [100]. As opposed to aspirin and reperfusion therapy, it is not crucial to introduce the ACE inhibitor in the hyperacute phase of acute MI.

Angiotensin receptor blockers (ARBs) are effective alternatives to ACE inhibitors for patients with LV dysfunction or HF following acute MI and provide similar long-term benefits [101]. However, combination therapy with ACE inhibitors and ARBs is not more effective [101]. Because of the larger evidence base and lower cost of ACE inhibitors, they are preferred over ARBs unless side effects to ACE inhibitors develop.

Aldosterone antagonists should also be considered for use in appropriate high-risk patients following STEMI, who are receiving adequate doses of ACE inhibitors. In the Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival (EPHESUS) trial, which included patients with an LV ejection fraction <40% following an MI and either HF symptoms or diabetes, eplerenone treatment (compared to placebo) was associated with a 15% reduction of the risk of mortality [102]. Because of its much lower cost, spironolactone may be considered as an alternative to eplerenone. Aldosterone antagonists should be avoided in patients with hyperkalemia or significant renal dysfunction (Table 187.7). Despite strong evidence and a class I recommendation, and in contrast to other post-MI recommendations, aldosterone antagonists remain dramatically underutilized in contemporary practice [103].

Nitrates

Nitrates dilate large coronary arteries and arterioles, peripheral veins, and to a lesser extent, peripheral arterioles. Venodilation decreases preload, thus reducing both myocardial oxygen demand and symptoms of pulmonary congestion that may complicate MI. The Gruppo Italiano per lo Studio della Sopravvivenza nell’Infarto (GISSI) 3 May favor leaving as GISSI 3 [104] and the Fourth International Study of Infarct Survival (ISIS-4) [105] trials collectively enrolled almost 80,000 patients and
evaluated the role of long-term (4- to 6-week) nitrate therapy post-MI. Neither study found a significant reduction in mortality with nitrates, although the ability to detect such a difference may have been reduced because more than 50% of patients received off-protocol nitrates. Although evidence from randomized clinical trials does not support routine long-term nitrate therapy for patients with uncomplicated MI, it is reasonable to give intravenous nitroglycerin for the first 24 to 48 hours in patients with acute MI who have HF, recurrent ischemia, or hypertension. Intravenous therapy is preferred in the early phases of MI because of its immediate onset of action and ease of titration. Nitrates should be avoided in patients with right ventricular infarction.

**Calcium Channel Blockers**

Calcium channel blockers block the entry of calcium into cells via voltage-sensitive calcium channels. In vascular smooth muscle cells, this causes coronary and peripheral vasodilation, whereas in cardiac tissue, it leads to depression of myocardial contractility, sinus rate, and atrioventricular (AV) nodal conduction. The dihydropyridine calcium channel antagonists, of which nifedipine is the prototype, cause coronary and peripheral artery dilation without blocking sinus or AV nodal function. As a result, the potential benefit of these agents is counterbalanced by reflex tachycardia. The short-acting preparations of nifedipine, in particular, appear to be dangerous in the setting of acute MI because they may cause rapid hemodynamic fluctuations. Sustained-release preparations of nifedipine, on the other hand, can be used safely in combination with a \( \beta \)-blocker. Amlodipine is a third-generation agent that causes less reflex tachycardia than other dihydropyridines, but with other calcium channel blockers, there is no documented benefit of this agent following MI; as such, it should only be used in patients who remain hypertensive after full-dose \( \beta \) blockade and ACE inhibition.

Diltiazem and verapamil slow HR and modestly reduce myocardial contractility, thereby decreasing myocardial oxygen demand. Of the two agents, verapamil has greater negative inotropic and chronotropic effects. A pooled analysis indicated that verapamil and diltiazem had no effect on mortality following acute MI, but that they did significantly reduce the rate of reinfarction (6.0% vs. 7.5%; \( p < 0.01 \) [106]). Despite an overall neutral effect of these agents on mortality, among patients with depressed LV function or evidence of HF, mortality is increased in patients treated with diltiazem or verapamil.

It should be emphasized that there have not been studies comparing the efficacy of verapamil or diltiazem to a \( \beta \)-blocker. \( \beta \)-blockers consistently reduce both mortality and reinfarction and should be recommended for all patients who can tolerate them. Verapamil or
diltiazem may be a reasonable alternative for patients who cannot tolerate a β-blocker, provided LV function is normal, but they should not be given routinely following MI.
ARRHYTHMIAS COMPLICATING ST ELEVATION MYOCARDIAL INFARCTION

Ventricular Arrhythmias

Ventricular arrhythmias are common following the onset of STEMI, but the impact on outcomes depends on the timing of onset (Table 187.6). Previously, it had been thought that VT occurring early after presentation (within the first 48 hours) did not influence long-term survival if it was rapidly terminated, whereas VT occurring beyond 48 hours had ominous implications. However, in a more recent analysis of 5,745 patients with STEMI from the Assessment of Pexelizumab in Acute Myocardial Infarction (APEX-AMI) trial [107], 5.7% developed VT or VF, which was associated with worse overall 90-day mortality (adjusted HR 3.63, 95% CI 2.59 to 5.09). Of those who developed ventricular arrhythmia, 64% occurred before the end of the index cardiac catheterization, and 90% occurred within the first 48 hours of STEMI presentation. Those patients whose ventricular arrhythmia occurred after index catheterization but less than 48 hours after presentation had an increased incidence of mortality at 90 days (adjusted HR 5.59, 95% CI 3.71 to 8.43).

MI, myocardial infarction.

VF is the primary mechanism of arrhythmic sudden death. In patients with acute MI, most episodes of VF occur early (<4 to 12 hours) after infarction. As with sustained VT, late VF occurs more frequently in patients with severe LV dysfunction or HF and is a poor prognostic marker. Patients with VF or sustained VT associated with symptoms or hemodynamic compromise should be cardioverted emergently. Underlying metabolic and electrolyte abnormalities must be corrected, and ongoing ischemia should be addressed. We aim to maintain the serum potassium level between 3.5 and 4.5 mEq per L and serum magnesium level of 2 mEq per L or more. Intravenous amiodarone is a particularly effective antiarrhythmic agent in patients with acute MI because it lowers HR and does not have pro-arrhythmic properties. Lidocaine remains an effective alternative if amiodarone is not tolerated or is unsuccessful in controlling the arrhythmia. Prophylactic use of antiarrhythmic agents, other than β-blockers, is not indicated.

Bradyarrhythmias

The usual cause of bradycardia is increased vagal tone or ischemia/infarction of conduction tissue. Sinus bradycardia is typically caused by irritation of cardiac vagal receptors, which are located most prominently on the inferior surface of the left ventricle (Table 187.6). Thus, this arrhythmia is usually seen with inferior MI. If the HR is extremely low (<40 to 50) and is associated with hypotension, intravenous atropine should be given.

Mobitz type I (Wenckebach) second-degree AV block is also very common among patients with inferior wall MI and may be caused by ischemia or infarction of the AV node or to increased vagal tone. The level of conduction block is usually located within the AV node, and therefore the QRS complex is narrow and the risk for progression to complete heart block is low. Atropine should be reserved for patients with hypotension or symptoms, and temporary pacing is rarely required. Mobitz type II block is observed much less often than Mobitz type I block in acute MI. As opposed to Mobitz type I block, Mobitz type II block is more frequently associated with anterior MI, an infranodal lesion, and a wide QRS complex. Because Mobitz type II block can progress suddenly to complete
heart block, a temporary pacemaker is indicated. Although complete heart block may occur with either inferior or anterior MI, the implications differ markedly depending on the location of the infarct. With inferior MI, heart block often progresses from first-(or Wenckebach) to third-degree AV block. The level of block is usually within or above the level of the AV node, the escape rhythm is often stable, and the effect is transient. Although temporary pacing is often indicated, a permanent pacemaker is rarely required. With anterior MI, complete heart block is usually a result of extensive infarction involving the bundle branches. The escape rhythm is usually unstable and the AV block permanent. Mortality is extremely high, and permanent pacing is almost always required for survivors.

Supraventricular Arrhythmias

Atrial fibrillation may occur in up to 15% of patients early after MI, but atrial flutter and paroxysmal supraventricular tachycardia are not commonly seen (Table 187.). Although atrial fibrillation is usually transient, it is a marker for increased morbidity and mortality, probably because it is associated with other adverse risk predictors such as LV dysfunction and congestive heart failure. Management of supraventricular arrhythmias in the setting of acute MI is similar to management in other settings; however, there should be a lower threshold for cardioversion, and the ventricular rate should be more aggressively controlled. Because of their beneficial effects for acute MI, β-blockers are the agents of choice for control rate. Diltiazem or verapamil may serve as alternatives for patients without significant HF or LV dysfunction, whereas digoxin should be reserved for patients with concomitant LV dysfunction. Of the antiarrhythmic agents available, amiodarone is safest for patients with recent MI because it has a low risk for causing arrhythmias.
Risk assessment is a continuous process that should be consistently reevaluated throughout the hospital stay. Continuing care must be individualized using lifestyle interventions, disease-modifying pharmacological therapies, and additional coronary revascularization when indicated. All patients with STEMI are considered at high risk and therefore warrant aggressive intervention for secondary prevention. All patients should undergo a transthoracic echocardiogram prior to hospital discharge to assess ventricular systolic function and to ensure that appropriate medications are initiated prior to discharge (i.e., ACE inhibitor, aldosterone antagonists) [27]. In addition, all patients without contraindications should be initiated on high-intensity statin therapy, and considered for ezetimibe, prior to discharge. Referral to cardiac rehabilitation is also indicated for all patients admitted with STEMI. The objectives of exercise-based cardiac rehabilitation are to increase functional capacity, decrease or alleviate anginal symptoms, reduce disability, improve quality of life, and reduce morbidity and mortality rates [109]. Finally, perhaps the most powerful secondary prevention strategy is smoking cessation. A meta-analysis of cohort studies in patients with ACS showed that smoking cessation reduces the subsequent cardiovascular mortality rate by almost 50% [110]. All of these interventions, together with appropriate patient and family education regarding medication adherence and timely follow-up, will serve to reduce rates of rehospitalization and improve patient outcomes (Table 187.7) [111,112].

patients who can be treated within 90 min of presentation in a high-volume center [38]

- Transfer to another facility for early nonemergent PCI should be considered following successful fibrinolytic therapy [68]
- The addition of clopidogrel to aspirin, antithrombins, and fibrinolytic therapy reduces recurrent MI and mortality [72,73]
- Prasugrel and ticagrelor represent alternatives to clopidogrel that reduce stent thrombosis and recurrent ischemic events, but at an increased risk for bleeding [75,76]
- Enoxaparin is superior to unfractionated heparin as an adjunct to fibrinolytic therapy but is associated with slightly more bleeding [79]
- Radial artery access (as opposed to femoral artery) may decrease bleeding complications and should be considered when feasible [40]
- β-Blockers improve long-term outcomes following STEMI but may increase risk when given early to unstable patients [93,94]
- ACE inhibitors prevent adverse remodeling after STEMI and reduce death and heart failure events [95]
- Aldosterone antagonists reduce mortality in patients with LV dysfunction or heart failure following MI but should be used in caution in individuals with renal dysfunction [98]

2. de Lemos JA, Braunwald E: ST segment resolution as a tool for assessing the efficacy of reperfusion therapy. *J Am Coll Cardiol*

The spectrum of acute coronary syndromes (ACS) ranges from unstable angina (UA) to non–ST-segment elevation myocardial infarction (NSTEMI) to ST-segment elevation myocardial infarction (STEMI) [1]. The latter condition is usually caused by acute total obstruction of a coronary artery [2,3], and urgent reperfusion is the mainstay of therapy. In contrast, the non–ST-segment elevation acute coronary syndromes (NSTE-ACS)—UA and NSTEMI—are usually associated with a severe, nonocclusive lesion in the culprit coronary artery [4].

Every year in the USA, approximately 1.1 million patients are hospitalized with ACS; about 800,000 of these patients suffer from MI, with approximately 25% of patients with MI presenting with STEMI [5]. Worldwide, these numbers are each several times the respective total in the USA. In recent years, numerous advances have advanced our understanding of the pathophysiology, diagnosis, risk stratification, and management of NSTE-ACS.

DEFINITION

ACS traditionally present with specific clinical features that can help distinguish ACS from stable angina: (a) occurring at rest (or with minimal exertion), usually lasting more than 20 minutes; (b) being severe
and of new onset (i.e., within 1 month); or (c) occurring with a crescendo pattern (i.e., more severe, prolonged, or frequent) [6]. In the absence of ST-segment elevations on electrocardiogram (ECG), these patients are characterized as having NSTE-ACS. Among patients with NSTE-ACS, those with evidence of myocardial necrosis on the basis of serum biomarkers have a diagnosis of NSTEMI, whereas those without evidence of myocardial necrosis are diagnosed with UA. With increasingly sensitive biomarkers for myocardial necrosis, among patients with NSTE-ACS the diagnosis of NSTEMI is increasing whereas that of UA is decreasing [7,8].
PATHOPHYSIOLOGY

The development of NSTE-ACS is caused by either a reduction in the supply of blood flow and oxygen, or an increase in myocardial oxygen demand, or both. The five broad etiologies are (a) plaque rupture or erosion with superimposed nonocclusive thrombus; (b) dynamic obstruction (i.e., coronary spasm); (c) progressive mechanical obstruction (i.e., restenosis); (d) inflammation and arteritis; and (e) conditions leading to increased myocardial oxygen demand, such as anemia, sepsis, or hypoxia [9]. Individual patients may have several of these processes contribute to the onset of their NSTE-ACS.

Plaque Rupture and Erosion

Atherosclerosis is a silent process that usually begins 20 to 30 years prior to a patient’s clinical presentation [10,11]. Plaque rupture and erosion can be precipitated by multiple factors, including endothelial dysfunction [12], plaque lipid content [13], local inflammation [14], coronary artery tone at the site of irregular plaques and local shear stress forces, platelet function [15,16], and the status of the coagulation system (i.e., a potentially prothrombotic state) [17,18]. These processes culminate in formation of platelet-rich thrombi at the site of the plaque rupture or erosion and the resultant ACS [19–21].

Thrombosis

Coronary artery thrombosis plays a central role during the pathogenesis of NSTE-ACS [4,19,20,22–26], as demonstrated in the Thrombolysis in Myocardial Infarction (TIMI) IIIA trial, in which 35% of patients had definite thrombus and an additional 40% had possible thrombus [4]. Thrombosis occurs in two interrelated stages: (a) primary hemostasis and (b) secondary hemostasis [27,28]. The first stage of hemostasis is initiated by platelets as they adhere to damaged vessels and form a platelet plug. With rupture or ulceration of an atherosclerotic plaque, the subendothelial matrix (e.g., collagen and tissue factor) is exposed to the circulating blood. Platelets then adhere to the subendothelial matrix via the glycoprotein (GP) Ib receptor and von Willebrand’s factor (platelet adhesion). After adhering to the subendothelial matrix, the platelet undergoes a conformational change from a smooth discoid shape to a spiculated form, which increases the surface area on which thrombin generation can occur. This leads to degranulation of the α- and dense granules and the subsequent release of thromboxane A2, adenosine
diphosphate (ADP), serotonin, and other platelet aggregatory and chemoattractant factors, as well as the expression and activation of GP IIb/IIIa receptors on the platelet surface such that it can bind fibrinogen. This process is called platelet activation. The final step is platelet aggregation, that is, the formation of the platelet plug. Fibrinogen (or von Willebrand’s factor) binds to the activated GP IIb/IIIa receptors of two platelets, thereby creating a growing platelet aggregate. Antiplatelet therapy has been directed at decreasing the formation of thromboxane A2 (aspirin), inhibiting the ADP pathway of platelet activation (thienopyridines), and directly inhibiting platelet aggregation.

**Secondary Hemostasis**

Simultaneous with the formation of the platelet plug, the plasma coagulation system is activated (Fig. 188.1). Following plaque rupture or ulceration, the injured endothelial cells on the vessel wall become activated and release protein disulfide isomerase, which acts to cause a conformational change in circulating tissue factor [29–32]. Tissue factor can then bind to factor VIIa and form a protein complex, leading to the activation of factor X. With the activation of factor X (to factor Xa), thrombin is generated and acts to cleave fibrinogen to form fibrin. Thrombin plays a central role during arterial thrombosis: (a) it converts fibrinogen to fibrin in the final common pathway for clot formation; (b) it is a powerful stimulus for platelet aggregation; and (c) it activates factor XIII, which leads to cross-linking and stabilization of the fibrin clot [27].
Coronary Vasoconstriction

Another etiologic factor of NSTE-ACS is dynamic obstruction, that is, coronary vasoconstriction. The process is identified in three settings: (a) vasospasm in the absence of obstructive plaque, (b) vasoconstriction in the setting of atherosclerotic plaque, and (c) microcirculatory angina. Vasospasm can occur among patients without coronary atherosclerosis or among those with a nonobstructive atheromatous plaque. Vasospastic angina appears to be caused by hypercontractility of vascular smooth muscle and endothelial dysfunction occurring in the region of spasm. Prinzmetal’s variant angina, with intense focal spasm of a segment of an epicardial coronary artery, is the prototypical example [33]. Such patients have rest pain accompanied by transient ST-segment elevation. Vasoconstriction more commonly occurs in the setting of significant coronary atherosclerotic plaque, especially those with superimposed thrombus. Vasoconstriction can occur as the result of local...
vasoconstrictors released from platelets, such as serotonin and thromboxane A2 [34–36]. Vasoconstriction can also result from a dysfunctional coronary endothelium, which has reduced the production of nitric oxide and increased the release of endothelin. Adrenergic stimuli, cold immersion [37], cocaine [38,39], or mental stress [40] can also cause coronary vasoconstriction among susceptible vessels. A third setting in which vasoconstriction is identified is microcirculatory angina (“syndrome X”). In this condition, ischemia results from constriction of the small intramural coronary resistance vessels [41]. Although no epicardial coronary artery stenoses are present, coronary flow is usually slowed and does not increase appropriately in response to a variety of signals.

**Progressive Mechanical Obstruction**

Another etiology of NSTE-ACS results from progressive luminal narrowing. This is most commonly seen in the setting of restenosis following percutaneous coronary intervention (PCI). However, angiographic [42] and atherectomy studies [43,44] have demonstrated that many patients without previous PCI show progressive luminal narrowing of the culprit vessel, likely related to rapid cellular proliferation, in the period preceding the onset of NSTE-ACS.

**Secondary Myocardial Infarction**

Secondary MI is defined as MI precipitated by conditions extrinsic to the coronary arteries, typically among patients with prior coronary stenosis and chronic stable angina. This change could occur either as a result of an increase of myocardial oxygen demand or as a decrease of coronary blood flow. Conditions that increase myocardial demand include tachycardia (e.g., a supraventricular tachycardia or new-onset atrial fibrillation with rapid ventricular response), fever, thyrotoxicosis, hyperadrenergic states, and elevations of left ventricular (LV) afterload, such as hypertension or aortic stenosis. Secondary MI can also occur as a result of impaired oxygen delivery, as in anemia, hypoxemia (e.g., caused by pneumonia or congestive heart failure), hyperviscosity states, or hypotension.
CLINICAL PRESENTATION AND DIAGNOSIS

History and Physical Examination

A description of “ischemic pain” is the hallmark of ACS. Ischemic chest pain is usually described as a discomfort or pressure (rarely as a pain) that is brought on by exertion and relieved by rest. It is generally located in the retrosternal region but sometimes in the epigastrium and frequently radiates to the anterior neck, left shoulder, and left arm. The physical examination may be unremarkable or may support the diagnosis of cardiac ischemia [45]. Signs that suggest ischemia are sweatiness, pale cool skin, sinus tachycardia, and a fourth heart sound. Elevated jugular venous pressure, a third heart sound, or rales on lung examination suggest the presence of heart failure complicating ACS.

Electrocardiogram

The ECG is the most widely used tool for the evaluation of ischemic heart disease and should be performed within minutes for patients presenting with suspected ACS. In NSTE-ACS, ST-segment depression (or transient ST-segment elevation) and T-wave changes occur in up to 50% of patients [46–48]. A normal ECG does not exclude ACS, and should be repeated at regular intervals among individuals with suspected ACS [7]. Additionally, a normal ECG may occur when the left circumflex coronary artery is occluded. Among patients with signs and symptoms of persistent myocardial ischemia, and the standard 12 lead ECG is nondiagnostic, then additional leads such as V₇ to V₉ to look for a posterior MI can be helpful. Among patients presenting with an inferior MI, checking right-sided leads (e.g., V₃R and V₄R) is helpful to screen for a concomitant right ventricular MI [7,8].

Cardiac Biomarkers

UA is not associated with any detectable damage to the myocyte. The diagnosis of NSTEMI is made if there is biochemical evidence of myocardial necrosis, preferably cardiac troponin T or I, in the appropriate clinical setting. The biomarker criteria include at least one value greater than the 99th percentile of the upper reference range. If the initial value is positive, a subsequent value must demonstrate an increase or decrease of ≥20% [7,49]. Although false-positive troponin elevations do occur [50], elevations of cardiac biomarkers in the absence of other clinical data consistent with an ACS usually do represent true myocardial
damage. In these cases, myocyte damage is because of etiologies besides atherosclerotic coronary artery disease, such as myocarditis; LV strain from congestive heart failure; hypertensive crisis; or right ventricular strain from pulmonary embolus [51].

A limitation of standard troponin assays is that they tend to have a low sensitivity in the first few hours of symptom onset. Thus, the current recommendation is to check troponin levels on presentation and then 3 to 6 hours after symptom onset (and repeat 6 hours later if the patient has any intermediate- or high-risk clinical features or any ECG changes). More sensitive assays show better diagnostic performance for patients presenting early after symptom onset [52,53]. High-sensitivity troponin assays, which have a coefficient of variation <10% at the 99th percentile of the upper limit of normal and can quantify troponin levels in >50% of a healthy cohort, can further improve the early diagnosis of MI. Using a high-sensitivity assay, values below the 99th percentile at presentation and 1 hour later have a negative predictive value >99.5%. Moreover, values below the limit of detection at presentation (seen in ~25% of patients) have a negative predictive value of >99.5% [54,55].

Cardiac Imaging

Cardiac imaging continues to assume increasing importance for the early diagnosis of patients presenting with suspected NSTE-ACS, especially when the ECG is normal, nonspecific, or obscured by a left bundle branch block or paced rhythm. Myocardial perfusion imaging using technetium sestamibi has been useful for patients presenting with chest pain in the emergency department without a diagnostic ECG or positive biomarkers to discriminate patients with coronary artery disease from those with noncardiac chest pain [56,57]. Similarly, echocardiography is useful to screen for regional or global LV dysfunction, which may help in establishing (or excluding) the diagnosis of ischemic heart disease for patients who present to the emergency department with chest pain [58]. Coronary computed tomography angiogram (CTA) has also been shown to be effective for excluding coronary artery disease among patients presenting to the emergency department with a low-risk story of chest pain, nondiagnostic ECG, and negative biomarkers [59]. All of these modalities can also assess LV function, a powerful determinant of subsequent prognosis after MI (and presumably after UA) [60–62]. Coronary angiography is also used to establish the diagnosis of ACS and is considered the gold-standard modality to define the extent of coronary
disease, and as a prelude to percutaneous revascularization (see section on treatment strategies and interventions) [4,47,63,64].
RISK STRATIFICATION

The process of risk stratification for patients with NSTE-ACS refers to two simultaneous processes (frequently carried out at the time of hospital presentation): (a) risk assessment (i.e., prediction of mortality/morbidity risk), and (b) selection of a management strategy (i.e., an early invasive vs. early conservative approach).

Risk assessment using clinical, electrocardiographic, and laboratory markers identifies which patients are at highest risk for adverse outcomes. Moreover, data from several trials have demonstrated that early risk assessment (especially using troponin) has also been useful for predicting which patients will derive the greatest benefit from more potent antithrombotic therapies, such as low-molecular-weight heparin (LMWH) and GP IIb/IIIa inhibitors. Risk assessment can similarly be used to determine the most appropriate level of care and monitoring (i.e., between the coronary intensive care unit and the step-down/telemetry unit). The “management strategy” refers to whether early angiography is performed (with revascularization as appropriate) directly following the index event or whether a conservative or ischemia-driven strategy is carried out, first with noninvasive assessment of residual ischemia, followed by angiography and revascularization only if recurrent ischemia is demonstrated (see section on, “Early Routine Invasive” vs. “Ischemia-Guided” Strategy of Coronary Angiography and Revascularization).

Risk Assessment Using Clinical Predictors

The initial clinical evaluation can be used to risk-stratify patients quickly and to assist with triage and early management strategy [7,8,65]. In addition to age, gender, and significant comorbidities, certain aspects of the clinical presentation can yield valuable information. High-risk patients can be identified by the presence of pain at rest and increasing frequency of symptoms leading up to the index event. Furthermore, tachycardia, hypotension, and signs of heart failure portend a poor prognosis. In particular, the Killip classification of heart failure severity has been shown to predict both short and long-term mortality for patients with NSTE-ACS [7,8,66,67].

Risk Assessment by Electrocardiography

The admission ECG can be quite useful for predicting early and long-term adverse outcomes [47,68]. In the Global Use of Strategies to Open Occluded Coronary Arteries (GUSTO) IIb study, The presence of ST
segment depressions of more than 0.5 mm was associated with a higher risk of 30-day and 6-month death or reinfarction compared with T-wave changes alone [68]. In the TIMI III registry of patients with NSTE-ACS, multivariable predictors of 1-year death or MI included left bundle branch block and ST-segment deviation of 0.5 mm or greater [46]. In contrast, the presence of isolated T-wave changes was not associated with a significantly increased risk of death or MI compared with no ECG changes [46].

The presence of ECG changes has also been associated with greater treatment benefit from more aggressive therapies. The presence of ST-segment deviation identified patients in both the Efficacy and Safety of Subcutaneous Enoxaparin in Non-Q-Wave Coronary Events (ESSENCE) and TIMI 11B trials who benefit the most from antithrombotic therapy with enoxaparin vs. unfractionated heparin (UFH) for NSTE-ACS [69,70]. Similarly, in both the Fragmin and Fast Revascularization during Instability in Coronary Artery Disease (FRISC) II, and Treat Angina with Aggrastat and Determine Cost of Therapy with an Invasive or Conservative Strategy (TACTICS)-TIMI 18 trials, an invasive strategy had a particular benefit for patients with ST-segment depression at presentation [71,72]. Thus, ST-segment deviation not only is a marker of increased risk for adverse outcomes but also identifies those patients who may derive greater benefit from aggressive antithrombotic and invasive therapy.

Risk Assessment by Cardiac Markers

Troponin

Patients with NSTEMI have a worse long-term prognosis than those with UA [73,74]. Patients with an elevated troponin, even with a normal CK-MB, have a significantly worse prognosis [75–77]. Beyond a binary positive vs. negative test result, there is a linear relationship between the level of troponin T or I in the blood and the subsequent risk of death: the higher the troponin, the higher the mortality risk (Fig. 188.2). Thus, troponin is useful not only for diagnosing infarction [78] but also for assessing risk among patients who present with NSTE-ACS. Given the enhanced sensitivity and specificity, troponin is the preferred marker of myocardial necrosis for both diagnosis and prognosis [7,8].
The presence of elevated troponin levels also correlates with the utility of particular therapies. In a trial examining the benefit of abciximab among patients with NSTE-AMI, the reduction of death or MI at 6 months was 70% for those who were troponin T positive, whereas there was no significant benefit for those who were troponin T negative \((p < 0.001)\) [79]. In the TIMI 11B trial, even when looking at patients who were CK-MB negative, those who were troponin I positive derived a significantly greater benefit from enoxaparin vs. UFH, compared with those who had both markers negative [80]. Research has also demonstrated that troponin levels are useful when choosing an invasive vs. conservative strategy for patients with NSTE-ACS. In both the FRISC II and TACTICS-TIMI 18 trials, patients who had a positive troponin T or I (including those who had very low levels of troponin) had a dramatic reduction of cardiac events after allocation to an invasive strategy [76,81]. Thus, there is evidence from multiple trials that the use of troponins can assist in both assessing the risk and determining which patients will accrue the most benefit from more potent antithrombotic agents and an invasive management strategy.

**Other Biomarkers**

NSTE-ACS patients with an elevated C-reactive protein (CRP) have an
increased risk of death and adverse cardiovascular events [82,83]. Even among patients with negative troponin I at baseline, CRP is able to discriminate high- and low-risk groups [84]. B-type natriuretic peptide (BNP) as well as N-terminal pro B-type natriuretic peptide (NT-proBNP), both biomarkers of LV wall stress, has also been shown to be a powerful predictor of mortality and heart failure among patients with NSTE-ACS [85–88]. Growth-differentiation factor 15 (GDF-15), a member of the transforming growth factor-β family induced by inflammation and cellular injury, has been shown to be a similarly powerful predictor of adverse cardiovascular outcomes after NSTE-ACS [89]. Researchers have even suggested that GDF-15 may be able to identify which NSTE-ACS patients will benefit most from an invasive treatment strategy. A retrospective analysis from the FRISC-II trial looked at GDF-15 levels among patients with NSTE-ACS and found that patients with markedly elevated GDF-15 levels had lower mortality when an invasive treatment strategy was used as opposed to conservative management. In contrast, among patients with ST-segment depression or an elevated troponin T level, those with a low GDF-15 level did not benefit from an invasive treatment strategy [90]. Larger prospective studies are needed to see if GDF-15 will be a useful tool when deciding on the management of patients with NSTE-ACS. Multimarker strategies have also been employed to improve risk stratification. The combination of troponin, CRP, and BNP can predict up to a 13-fold gradient of mortality post-ACS [91]. However, it should be noted that although CRP and BNP can be used as prognostic indicators, only troponin and potentially GDF-15 can identify patients who may derive greater benefit from specific interventions.

Combined Risk Assessment Scores

The current AHA/ACC and ESC guidelines for the management of NSTE-ACS recommend the use of risk scores to facilitate decisions regarding triage and management strategy [7,8]. The TIMI risk score uses readily available clinical factors, ECG changes, and cardiac markers. It consists of the following seven risk factors: age 65 years or older, more than three risk factors for coronary artery disease, documented coronary artery disease at catheterization, ST-segment deviation of 0.5 mm or greater, more than two episodes of angina in the past 24 hours, aspirin use within the prior week, or elevated serum cardiac markers. Use of this scoring system was able to risk-stratify patients across a 10-fold gradient of risk, from 4.7% to 40.9% (p <0.001) [92]. Most importantly, this risk score identified patients who derived the greatest benefit from enoxaparin vs. UFH [92], from use of a GP IIb/IIIa inhibitor [93], and from an early invasive management strategy [72].
The GRACE (Global Registry of Acute Coronary Events) risk score incorporates multiple characteristics on admission to identify patients at greatest risk of in-hospital and 6-month mortality following an ACS. The model includes age; heart rate; systolic blood pressure; serum creatinine; presence and severity of heart failure according to Killip class, whether or not there was a cardiac arrest at admission; ST-segment deviation; and elevated cardiac markers at presentation [94,95]. When applied to patients with NSTE-ACS, the GRACE risk score is also able to identify those patients most likely to benefit from an early invasive strategy. In the Timing of Intervention in Patients with Acute Coronary Syndromes (TIMACS) trial, NSTE-ACS patients with a GRACE risk score of greater than 140 (the highest risk tertile) had a 35% reduction in the primary end point (composite of death, MI, or stroke) with early coronary angiography (median time, 14 hours) when compared to delayed intervention (median time, 50 hours): 13.9% vs. 21%; \( p = 0.006 \). In patients with a GRACE risk score of less than 140, there was no difference between the two groups: 7.6% vs. 6.7%; \( p = 0.48 \) [96]. Therefore, combined risk assessment scores can not only identify those patients at the highest risk for an adverse cardiovascular event, but can also assist the clinician with management decisions regarding antithrombotic therapy and coronary angiography.
MEDICAL THERAPIES

Treatment Goals

The treatment objectives for patients with NSTE-ACS are focused on stabilizing and “passivating” the acute coronary lesion, treatment of residual ischemia, and long-term secondary prevention. Antithrombotic therapy (e.g., aspirin, P2Y12 ADP receptor blockers such as ticagrelor, prasugrel and clopidogrel, anticoagulants, and GP IIb/IIIa inhibitors) is used to prevent further clotting in the coronary artery and allow endogenous fibrinolysis to dissolve the thrombus and reduce the degree of coronary stenosis. Antithrombotic therapy is continued long term so that if future events occur, the degree of thrombosis is reduced. Anti-ischemic therapies (e.g., β-blockers, nitrates, and sometimes calcium channel blockers) are used to reduce myocardial oxygen demand. Coronary revascularization is frequently needed to treat recurrent or residual ischemia. After stabilization of the acute event, the many factors that led up to the event need to be addressed. Treatment of atherosclerotic risk factors such as hypercholesterolemia, hypertension, and smoking, which contributes to stabilization of the cholesterol-laden plaque and healing of the endothelium, is critical.

Antiplatelet Therapy

Aspirin

Aspirin is a cornerstone of therapy for patients who present with NSTE-ACS. Through irreversible inhibition of cyclooxygenase (thus limiting the production of thromboxane A2), aspirin decreases platelet activation and has demonstrated clear beneficial effects for patients who present with NSTE-ACS [74,97–99]. The randomized Clopidogrel and Aspirin Optimal Dose Usage to Reduce Recurrent Events - Seventh Organization to Assess Strategies in Ischemic Syndromes (CURRENT-OASIS 7) trial evaluated 25,086 ACS patients (who were referred for an invasive strategy) and demonstrated no differences of outcomes between the low-dose (75 to 100 mg) and high-dose (300 to 325 mg) aspirin groups. Importantly, each arm received an initial loading dose of aspirin of at least 300 mg on day 1 [100]. These results were similar for the prespecified subset of individuals who underwent PCI [101]. A subsequent meta-analysis demonstrated comparable benefit between low-dose (less than 160 mg) and high-dose (greater than or equal to 160 mg) aspirin with an increased
risk of bleeding in the high-dose group [102]. Additionally, patients treated with ticagrelor in the Platelet Inhibition and Patient Outcomes (PLATO) trial had better outcomes when they were concomitantly treated with low vs. high maintenance dose of aspirin [103]. Thus, for patients presenting with NSTE-ACS, an initial loading dose of non-enteric coated aspirin of 325 mg followed by maintenance dose of 75 to 81 mg daily is a reasonable approach [7,8]. For patients with an allergy to aspirin, a loading dose of clopidogrel followed by daily maintenance dosing is a reasonable alternative [7].

**P₂Y₁₂ ADP Receptor Blockers**

Clopidogrel is a thienopyridine derivative that inhibits platelet activation and aggregation by irreversibly inhibiting the binding of ADP to the P₂Y₁₂ receptor on the surface of the platelet. In the Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial the addition of clopidogrel plus aspirin led to a 20% reduction of recurrent cardiovascular events when compared with aspirin alone for 12,562 randomized NSTE-ACS patients [104]. For patients who underwent PCI, those treated with clopidogrel experienced a 30% reduction of ischemic events [105]. The combination of clopidogrel plus aspirin was however associated with a relative 35% increase of major bleeding (using the CURE trial definition), but the absolute increase was only 1% (from 2.7% to 3.7%). Furthermore, using the standard TIMI definition of bleeding, there was no significant increase of major bleeding risk and no increase of intracranial hemorrhage.

Clopidogrel is an inactive prodrug that requires hepatic metabolism via the cytochrome P450 (CYP) system to produce the active metabolite (Table 188.1). Roughly, 85% of the prodrug is hydrolysed to an inactive metabolite by circulating esterases [8,106]. There are several notable pharmacogenetic and drug–drug interactions for clopidogrel that can affect patient outcomes. Approximately 25% to 30% of the population has a reduced-function genetic variant of CYP2C19, a member of the CYP450 enzyme family. When treated with clopidogrel, these individuals have lower circulating levels of the clopidogrel active metabolite, thereby leading to less platelet inhibition, and a higher rate of ischemic events including stent thrombosis [107–109].

**p. 1792**

Metabolism of clopidogrel may also be affected by certain drugs. Several pharmacodynamic studies had shown that proton pump inhibitors (PPIs) that inhibit CYP2C19 could decrease clopidogrel activity. However, the safety of combination therapy with clopidogrel and omeprazole was demonstrated in the Clopidogrel and the Optimization of Gastrointestinal Events Trial (COGENT), which randomized patients to clopidogrel alone or a combination pill of clopidogrel plus omeprazole following PCI. There was no difference of cardiovascular outcomes over 6 months, although they did note a significant reduction in GI events among patients taking the PPI [110]. Given the dependence of clopidogrel metabolism on the CYP450 system and the large number of PPIs available, including some that do not inhibit CYP2C19, extra vigilance should be taken when prescribing other drugs with clopidogrel.

Prasugrel is a third-generation P₂Y₁₂ ADP receptor blocker. Although also a prodrug and an irreversible P₂Y₁₂ inhibitor, prasugrel has a quicker onset of action when compared to clopidogrel (30 to 90 minutes for prasugrel vs. 2 to 6 hours for clopidogrel). Prasugrel has more predictable and more potent platelet inhibition than clopidogrel [106]. The Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel - Thrombolysis in Myocardial Infarction (TRITON-TIMI) 38 compared prasugrel to clopidogrel in 13,608 ACS patients who were scheduled to undergo PCI. Notably, study medication
was administered after coronary anatomy was known, either during or after PCI. Patients receiving prasugrel had a 19% reduction of the rate of cardiovascular death, MI, and stroke (9.9% vs. 12.1%; \( p < 0.001 \)) as well as a 52% reduction in stent thrombosis (1.1% vs. 2.4%; \( p < 0.001 \)) \cite{111,112}. These positive effects come at the price of significantly increased rates of major bleeding with prasugrel after PCI (2.4% vs. 1.8%; \( p < 0.001 \)) \cite{111}. Comparable effects to the overall trial results were seen among the 10,074 patients with NSTE-ACS. Prasugrel is contraindicated for patients with a history of cerebrovascular events due to net harm in this subgroup, whereas there was no clinical benefit for patients older than 75 years of age or for patients who weighed less than 60 kg \cite{111}. The Targeted Platelet Inhibition to Clarify the Optimal Strategy to Medically Manage Acute Coronary Syndromes (TRILOGY ACS) trial evaluated aspirin plus either clopidogrel or prasugrel in NSTE-ACS patients managed medically without revascularization. There was no difference in ischemic or bleeding events \cite{113}. As a result of these findings, for patients treated with PCI who are not at high risk for bleeding, prasugrel is preferred over clopidogrel \cite{7}.

Ticagrelor is another oral P2Y12 ADP inhibitor; however, unlike clopidogrel or prasugrel, it has reversible binding and is administered twice daily. Similar to prasugrel, ticagrelor has a faster and more predictable onset of action than clopidogrel (Table 188.1). The PLATO trial compared clopidogrel and ticagrelor in 18,624 patients presenting with ACS \cite{114}. Similar to the overall trial, for the subset of 11,080 NSTE-ACS patients, ticagrelor reduced the primary end point of CV death, MI, or stroke (10.0% vs. 12.3%, \( p = 0.0013 \)) when compared with clopidogrel. There was also a reduction in the rates of CV death (3.7% vs. 4.9% \( p = 0.007 \)), and all-cause mortality (4.3% vs. 5.8% \( p = 0.002 \)) \cite{115}. Bleeding outcomes were also similar to the overall trial for the subset of patients with NSTE-ACS: No overall difference of major bleeding, but the ticagrelor group did have a higher rate of non-CABG related major bleeding (4.8% vs. 3.8% \( p = 0.0139 \)). The lower event rates with ticagrelor vs. clopidogrel were independent of revascularization status within the first 10 days following randomization \cite{115}. Two additional notable side effects observed from the PLATO trial were dyspnea (occurred in 15% and led to drug discontinuation in <1% of patients) and asymptomatic ventricular pauses which were not associated with increased rates of syncope or pacemaker implantation \cite{114}. Ticagrelor is preferred over clopidogrel for patients treated with medical therapy or with PCI \cite{7}.

Cangrelor is an intravenous P2Y12 ADP inhibitor with a short half-life (less than 10 minutes) that has a fast and predictable onset and offset of action. Within minutes of an initial bolus the desired antiplatelet effect is achieved, and within 60 minutes of stopping the infusion platelet
function is restored. In the CHAMPION-PHOENIX trial, there was a significant reduction of the composite of death from any cause, myocardial infarction, ischemia-driven revascularization, or stent thrombosis at 48 hours with cangrelor compared to clopidogrel (4.7% vs. 5.9% \( p = 0.005 \)), with the results mainly driven by periprocedural stent thrombosis and MI. There was no increase in the rate of primary safety end point, GUSTO-defined severe bleeding (0.16% for the cangrelor group vs. 0.11% for the clopidogrel group \( p = 0.44 \)) [116].

Cangrelor’s short half-life with quick onset and offset make it an appealing option for use as a bridge for patients planned for surgery. The phase II pharmacodynamic BRIDGE study evaluated the use of cangrelor as a bridge to CABG for 210 patients (More than 1/3 with NSTE-ACS) who had an indication for thienopyridine treatment [117]. Continuous infusion at a dose of 0.75 \( \mu \)g/kg/min provided comparable platelet inhibition to daily thienopyridine therapy. There was no increase of major bleeding complications; however, the study was not powered for clinical end points. The use of cangrelor as a bridge for noncardiac surgery or for other clinical scenarios appears to be an attractive strategy, although it has not yet been evaluated in these additional settings [106].

Although the use of \( P_2Y_{12} \) inhibition in NSTE-ACS has become standard of care, the optimal timing of \( P_2Y_{12} \) inhibitor administration (before or after coronary angiography) remains quite uncertain [118,119]. Previous guidelines recommended that \( P_2Y_{12} \) inhibitor therapy be initiated as soon as possible after the diagnosis of NSTE-ACS [120,121]. However, these recommendations were based on data from studies of clopidogrel, which is a prodrug and for which the clinical data suggested a benefit to pretreatment [105,122]. Subsequent to the previous guidelines, the only randomized controlled trial to evaluate the effect of pretreatment with \( P_2Y_{12} \) inhibition (the ACCOAST trial) demonstrated no ischemic benefit with the administration of prasugrel prior to angiography, whereas pretreatment was associated with increased bleeding [123]. As a result, prasugrel is not recommended prior to coronary angiography for patients with NSTE-ACS. In contrast, there are no randomized controlled data to support or refute pretreatment with either clopidogrel or ticagrelor. As a result, the current guidelines provide no substantive recommendations regarding when to initiate clopidogrel or ticagrelor for patients with NSTE-ACS undergoing an invasive strategy, whereas for patients undergoing a noninvasive strategy, \( P_2Y_{12} \) inhibition with clopidogrel or ticagrelor is recommended as soon as the diagnosis of NSTE-ACS is made [7,8].

Duration of Dual Antiplatelet Therapy
For patients who have tolerated dual antiplatelet therapy well for 12 months, it may be reasonable to continue dual antiplatelet therapy for longer than 12 months [124]. For patients who had been on dual antiplatelet therapy for 12 months following PCI, the Dual Antiplatelet Therapy (DAPT) study demonstrated a significant reduction in major adverse cardiovascular and cerebrovascular events with prolonged dual antiplatelet therapy (for an additional 18 months) compared to aspirin alone [125]. This benefit was consistent for the subgroup of patients with a prior MI. This concept was reaffirmed in the Prevention of Cardiovascular Events in Patients with Prior Heart Attack Using Ticagrelor Compared to Placebo on a Background of Aspirin—Thrombolysis in Myocardial Infarction 54 (PEGASUS-TIMI 54) [126]. The combination of aspirin plus 2 different doses of ticagrelor (60 or 90 mg twice daily) reduced the composite outcome of cardiovascular death, MI, or stroke when compared with aspirin plus placebo among patients with a prior MI more than 1 year before study entry (Fig. 188.3). A meta-analysis of DAPT for patients with prior MI also showed similar benefit with prolonged DAPT vs. aspirin alone [127]. This benefit was seen across several high-risk subgroups including patients with diabetes, multivessel coronary artery disease, renal impairment, and peripheral arterial disease [128]. Importantly, prolonged DAPT did increase the overall risk of bleeding (although there was no increase in the risk of intracranial hemorrhage or of fatal bleeding). [125–127]. Thus, the increased risk of bleeding must be weighed against the ischemic benefit, with treatment decisions tailored to the individual patient, potentially targeting individuals with risk factors associated with increased recurrent events [128].

**FIGURE 188.3** Kaplan–Meier curves demonstrating the benefit of ticagrelor (60 mg or 90 mg) vs. placebo in reducing rates of major adverse
cardiovascular events

Glycoprotein IIb/IIIa Inhibitors

Glycoprotein (GP) IIb/IIIa inhibitors prevent the final common pathway of platelet aggregation, that is, fibrinogen-mediated cross-linkage of platelets via the GP IIb/IIIa receptor (Fig. 188.1). Currently available GP IIb/IIIa inhibitors are all administered intravenously and include abciximab, eptifibatide, and tirofiban. Abciximab is a monoclonal antibody Fab fragment directed at the GP IIb/IIIa receptor, whereas eptifibatide, a synthetic heptapeptide, and tirofiban, a nonpeptide molecule, are antagonists of the GP IIb/IIIa receptor whose structure mimics the arginine–glycine–aspartic acid amino acid sequence by which fibrinogen binds to the GP IIb/IIIa receptor.

The efficacy of the GP IIb/IIIa inhibitors for the treatment of NSTEMIs has been evaluated by several studies. A meta-analysis of six randomized controlled trials (with nearly 30,000 NSTE-ACS patients) demonstrated a modest 9% relative reduction of rates of 30 day death or MI (10.7% vs. 11.5% \( p = 0.02 \)) with the use of GP IIb/IIIa inhibitors. Notably, this benefit was predominantly seen among individuals who underwent PCI \[129\]. These trials, however, were largely performed before the era of routine P2Y12 inhibition. The ISAR-REACT 2 trial addressed whether GP IIb/IIIa inhibition with abciximab provided additional benefit for 2,022 NSTE-ACS patients who were scheduled to undergo PCI after pretreatment with clopidogrel. The use of abciximab was associated with a 25% reduction of adverse cardiovascular events (8.9% vs. 11.9%, \( p = 0.03 \)). The benefits afforded by the addition of abciximab to clopidogrel were limited to patients with an elevated troponin \[130\].

Although these earlier trials demonstrated the benefit of GP IIb/IIIa inhibition for the management of patients with NSTEMIs undergoing PCI, the optimal timing for drug initiation was unclear. Subsequent randomized controlled trials compared upstream GP IIb/IIIa inhibitor initiation prior to angiography vs. deferred initiation at the time of PCI. The Acute Catheterization and Urgent Intervention Triage Strategy (ACUITY) Timing trial demonstrated that a deferred treatment strategy was noninferior to the upstream treatment strategy for ischemic events...
(7.9% vs. 7.1%, relative risk 1.12, 95% CI 0.97 to 1.29, \(p = 0.044\) for noninferiority, \(p = 0.13\) for superiority), whereas the deferred treatment strategy was associated with lower bleeding rates (4.9% vs. 6.1%, \(p < 0.001\) for noninferiority, \(p = 0.009\) for superiority) [131]. Similar findings were observed from the more recent Early Glycoprotein IIb/IIIa Inhibition in Non–ST-Segment Elevation Acute Coronary Syndrome (EARLY ACS) trial which evaluated the use of routine use of upstream GP IIb/IIIa inhibitor eptifibatide vs. delayed provisional use of the medication at the time of PCI [132]. There was no significant difference of the composite rate of death, MI, urgent revascularization, or thrombotic complication during PCI between the two groups, whereas the patients randomized to upstream eptifibatide had higher rates of non–life-threatening bleeding and more blood transfusions.

Based on these data demonstrating no benefits but increased bleeding with upstream initiation of GPIIb/IIIa inhibitors, their role prior to PCI is limited. The current AHA/ACC guidelines provide a class IIb recommendation that for high-risk patients (e.g., those with positive troponin) treated with an early invasive strategy and dual antiplatelet therapy, a GP IIb/IIIa inhibitor may be considered as part of initial antiplatelet therapy [7]. Alternatively, the current ESC guidelines recommend against the use of GP IIb/IIIa inhibitors for patients in whom the coronary anatomy is not known, and provide a class IIa recommendation for their use during PCI in bailout situations or for thrombotic complications [8].

**Vorapaxar**

Vorapaxar is an oral selective platelet thrombin receptor PAR-1 inhibitor that prevents thrombin mediated platelet activation. The Thrombin Receptor Antagonist for Clinical Event Reduction in Acute Coronary Syndrome (TRACER) trial randomized 12,944 patients with NSTE-ACS to either vorapaxar (40 mg loading dose followed by 2.5 mg daily) or placebo [133]. Most patients were treated with aspirin (97%) and clopidogrel (92%). There was no significant difference in ischemic events between the two treatment groups (18.5% vorapaxar vs. 19.9% placebo; \(p = 0.07\)); however, there were significantly increased rates of moderate or severe bleeding for the vorapaxar group (7.2% vs. 5.2%; HR 1.35; 95% CI, 1.16 to 1.58; \(p < 0.001\)). Rates of intracranial hemorrhage were also significantly higher with vorapaxar compared to placebo (1.1% vs. 0.2%; HR 3.39; 95% CI, 1.78 to 6.45; \(p < 0.001\)).

In a non-acute setting, the Thrombin Receptor Antagonist in Secondary Prevention of Atherothrombotic Ischemic Events (TRA 2P—TIMI 50) trial evaluated the effect of vorapaxar (2.5 mg once daily) for the secondary prevention of ischemic events among patients with a
history of MI, stroke, or peripheral arterial disease [134]. There was a reduction of ischemic events with vorapaxar compared with placebo (9.3% vs. 10.5%; \( p < 0.001 \)) at the expense of excess moderate or severe bleeding (4.2% vs. 2.5%; \( p < 0.001 \)) and increased intracranial bleeding (1% vs. 0.5%; \( p < 0.001 \)). Among the 17,779 patients with a history of MI, the vorapaxar group had a lower rate of ischemic events (8.1% vs. 9.7%; \( p < 0.001 \)), but also had higher rates of moderate or severe bleeding (3.4% vs. 2.1%; \( p < 0.001 \)).

**Anticoagulation**

**Heparin**

Among patients with NSTE-ACS, anticoagulation on top of antiplatelet therapy reduces the risk of events [135]. Unfractionated heparin (UFH) is a widely used anticoagulant that works by blocking both thrombin and factor Xa. UFH is administered as a continuous infusion in patients with ACS owing to its short half-life. A meta-analysis showed a 33% reduction in death or MI when comparing UFH plus aspirin vs. aspirin alone [136].

The optimal regimen appears to be weight-adjusted dosing (60 units/kg bolus with a maximum of 4,000 units and 12 units/kg/h infusion with a maximum of 1,000 units per hour), with frequent monitoring of the activated partial thromboplastin time (aPTT) (every 6 hours until in the target range and every 12 to 24 hours thereafter), and titration using a standardized nomogram, with a target range of aPTT between 1.5 and 2.5 times control or approximately 50 to 70 seconds. UFH should be continued for 48 hours or until PCI is performed [7].

**Low-Molecular-Weight Heparin**

Compared with UFH, LMWH has a higher ratio of anti-Xa to antithrombin activity, and thus has more effective inhibition of thrombin generation [137]. LMWH has additional potential advantages over standard UFH. LMWH has less binding with platelet factor 4 (PF4), a heparin-neutralizing protein, which may explain the lower rates of heparin induced thrombocytopenia (HIT) with LMWH vs. UFH [137]. Additionally, higher bioavailability and a more predictable dose response allow for weight-based subcutaneous dosing without frequent monitoring. The recommended enoxaparin dose is 1 mg/kg every 12 hours. Importantly, because enoxaparin is affected by renal dysfunction, dose adjustment is necessary for patients with reduced renal function (creatinine clearance 15 to 30 mL per min: dose 1 mg/kg once daily), and for patients with severe renal dysfunction (creatinine clearance < 15 mL per minute) LMWH should not be used.
Several trials have compared UFH with enoxaparin in patients with NSTE-ACS. The earlier studies, Efficacy and Safety of Subcutaneous Enoxaparin in Non-Q-Wave Coronary Events (ESSENCE) and TIMI 11b, demonstrated a reduction of ischemic events among patients treated with enoxaparin vs. UFH [70,138]. Importantly, these trials were conducted on a background of predominantly noninvasive management strategies. In contrast, the subsequent Superior Yield of the New Strategy of Enoxaparin, Revascularization and Glycoprotein IIb/IIIa Inhibitors (SYNERGY) trial, conducted among high-risk NSTE-ACS patients who were planned for an early invasive strategy, demonstrated no reduction in ischemic events with enoxaparin vs. UFH, but that enoxaparin was associated with increased bleeding (9.1% vs. 7.6%; $p = 0.008$) [139]. Given the differing results, a meta-analysis was performed including 49,088 ACS patients that demonstrated a significant reduction of ischemic events with enoxaparin vs. UFH and no differences of bleeding [140]. Similar results were noted for the subset of NSTE-ACS patients; enoxaparin reduced ischemic events (odds ratio 0.90; 95% CI 0.81 to 0.996, $p = 0.043$), without a significant increase of major bleeding (odds ratio 1.13, 95% CI 0.84 to 1.54, $p = 0.419$).

### Fondaparinux

Fondaparinux is a synthetic pentasaccharide and a specific factor Xa inhibitor. In the Organization to Assess Strategies in Ischemic Syndromes (OASIS)-5 study, fondaparinux was found to be noninferior to enoxaparin in terms of ischemic events and nearly halved the rate of major bleeding over the first 9 days in patients with NSTE-ACS [141]. By 30 days, mortality was significantly lower in the fondaparinux arm (hazard ratio 0.83; 95% CI 0.71 to 0.97; $p = 0.02$). Notably, in the subset of patients undergoing PCI, fondaparinux was associated with an increased risk of catheter-related thrombi. Standard-dose UFH during PCI appeared to minimize this risk [142], and consequently, the AHA/ACC and ESC recommend that standard-dose UFH be used during PCI for patients treated with fondaparinux beforehand [7,8].

### Bivalirudin

Bivalirudin is another antithrombotic drug used in the treatment of NSTE-ACS, which acts by directly inhibiting thrombin and thus inhibiting clot formation. Bivalirudin was evaluated in the Acute Catheterization and Urgent Intervention Triage Strategy (ACUITY) trial,
which randomized 13,819 patients with NSTE-ACS, who were to be managed with an early invasive strategy, to one of three treatments: UFH or enoxaparin plus a GP IIb/IIIa inhibitor, bivalirudin plus a GP IIb/IIIa inhibitor, or bivalirudin alone. The study found no differences of the primary end point of death, MI, unplanned revascularization for ischemia, and major bleeding at 30 days between bivalirudin plus GP IIb/IIIa inhibitor and UFH/enoxaparin plus a GP IIb/IIIa inhibitor [143]. For the bivalirudin-alone group, when compared with the group receiving UFH/enoxaparin plus a GP IIb/IIIa inhibitor, there was no difference of the composite ischemic end point, but there was a lower rate of bleeding (3.0% vs. 5.7%; \( p < 0.001 \)). Similar results were noted for the Intracoronary Stenting and Antithrombotic Regimen: Rapid Early Action for Coronary Treatment 4 (ISAR-REACT 4) trial [144]. A meta-analysis including 16 trials comparing bivalrudin-based regimens with heparin-based regimens demonstrated that bivalrudin was associated with a reduction of bleeding events, but with an increased risk of MI and stent thrombosis [145]. The Minimizing Adverse Hemorrhagic Events by Transradial Access Site and Systemic Implementation of Angiox (MATRIX) study demonstrated no benefit with bivalrudin for either major adverse cardiovascular events or for net clinical adverse events (a composite of major bleeding and major adverse cardiovascular events) [146]. The AHA/ACC guidelines recommend that bivalirudin only be used for patients managed with an early invasive strategy whereas the ESC guidelines recommend bivalirudin as an alternative to UFH-GP IIb/IIIa inhibitors during PCI [7,8].

**Oral Anticoagulation**

Oral anticoagulation with warfarin following ACS has been examined by several trials, because prolonged treatment might extend the benefits of early anticoagulation. The Warfarin Reinfarction Study II randomized 3,630 patients with acute MI to three arms: aspirin 160 mg daily; warfarin alone (target INR 2.8 to 4.2; mean 2.8); and warfarin (target INR 2.0 to 2.5; mean 2.2) plus 75 mg aspirin [147]. When compared with aspirin alone, the combination of warfarin plus aspirin lowered the rate of ischemic events, but at the expense of increased bleeding.

Two more recent trials have evaluated the addition of non-vitamin K antagonist oral anticoagulants (NOACs) to dual antiplatelet therapy following ACS. The Apixaban for Prevention of Acute Ischemic Events (APPRAISE) 2 trial compared the addition of apixaban 5mg twice daily to placebo in addition to standard antiplatelet therapy following ACS. The trial was stopped early to a significant increase of bleeding without a reduction of ischemic events [148]. The Anti-Xa Therapy to Lower Cardiovascular Events in Addition to
Aspirin with or without Thienopyridine Therapy in Subjects with Acute Coronary Syndrome (ATLAS ACS 2)—TIMI 51 evaluated the effect of adding rivaroxaban (2.5 or 5 mg twice daily) vs. placebo in 15,526 patients with a recent ACS. Roughly 50% of the population had NSTE-ACS and 93% were on clopidogrel in addition to aspirin, and it included patients with a history of intracranial bleeding, ischemic stroke, or TIA [149]. At mean follow-up of 13 months, the addition of rivaroxaban led to a 16% lower rate of death, MI, or stroke at the expense of increased bleeding. The 2.5 mg dose led to a significant 32% reduction in all-cause mortality whereas the 5 mg dose did not. Although both doses led to a significant increase of bleeding (including intracranial bleeding), the 2.5 mg dose had less of an increased bleeding risk than the 5 mg dose. As a result, the 2.5 mg twice daily dose is currently available in Europe with a class IIb recommendation from the ESC for patients with a recent NSTE-ACS, to be used in combination with aspirin and clopidogrel. It is not recommended to be used in combination with ticagrelor or prasugrel and is contraindicated in patients with a history of ischemic stroke or TIA [8]. Rivaroxaban has not been approved for this indication in the USA and is not included in the current AHA/ACC guidelines. However, supporting the benefit of this approach, the results of the COMPASS trial have recently been announced in which very low-dose rivaroxaban added to aspirin was superior to low-dose aspirin monotherapy in patients with a history of vascular disease.

Thrombolytic Therapy for NSTE-ACS

Because thrombolytic therapy is beneficial for the treatment of patients with acute MI presenting with ST-segment elevation, it was hoped that it might play a role in other ACS. In TIMI IIIB, 1,473 patients with UA and non–Q-wave MI were treated with aspirin and heparin and were randomized to receive either tissue-type plasminogen activator (t-PA) or placebo. No difference was found for the primary end point comparing t-PA with placebo: the incidence of death, postrandomization infarction, or recurrent, objectively documented ischemia through 6 weeks (54.2% for t-PA and 55.5% for placebo; p = not significant [NS]) [47].

The TIMI IIIB results are corroborated by the Fibrinolytic Therapy Trialists’ Collaborative Group overview, in which patients with suspected MI and ST-segment depression on the ECG had a higher mortality when treated with a fibrinolytic [150,151]. Accordingly, fibrinolytic therapy is not indicated in NSTE-ACS [7].
Anti-Ischemic Therapy

Oxygen

Patients who are in respiratory distress and/or have an arterial oxygen saturation <90% should receive supplemental oxygen [7,8]. Previous guidelines recommended for the routine use of supplemental oxygen in all patients with NSTE-ACS during the first 6 hours after presentation, even in the absence of low arterial oxygen saturation [120]. In normoxic NSTE-ACS patients, there is no evidence that routine supplemental oxygen is beneficial; however, there is evidence of potential harm with routine supplemental oxygen among normoxic STEMI patients [152].

Nitrates

Nitrates can be helpful for the management of ischemic symptoms of patients with NSTE-ACS. Importantly, they are provided for symptom relief and do not impart a mortality benefit. Both the Gruppo Italiano per lo Studio della Sopravvivenza nell’Infarto miocardico (GISSI) 3 and International Study of Infarct Survival (ISIS) four trials failed to demonstrate a survival benefit with nitrates for patients with confirmed or suspected ACS [153,154]. If there is persistent pain or hypertension after three sublingual tablets and initiation of β-blockade, intravenous nitroglycerin is recommended [7]. Nitrates should not be given to patients who have recently taken a phosphodiesterase inhibitor because of an increased risk of hypotension.

β-Blockers

β-Blockers lower heart rate, blood pressure, and contractility, leading to decreased myocardial oxygen consumption. A recent meta-analysis demonstrated that early initiation of β-blockade was associated with a reduction of ischemic events and a modest reduction in near term all-cause mortality [155]. The Clopidogrel and Metoprolol in Myocardial Infarction Trial (COMMIT) demonstrated the importance of selecting the right population for early initiation of β-blockade in ACS [156]. In the overall population of 45,852 patients, the beneficial effects of metoprolol on reinfarction and ventricular fibrillation were balanced by an increased risk of cardiogenic shock. When the population was stratified according to risk of cardiogenic shock, those considered low risk demonstrated a significant benefit associated with early initiation of β-blockade. The clinical features identified as high risk for cardiogenic shock included age >70 years, systolic blood pressure <120 mmHg, heart rate >110 beats per
minute, and overt heart failure on initial examination (Killip class III). The current guidelines recommend for initiation of oral $\beta$-blockade within the first 24 hours for patients who are not in heart failure, in a state of low cardiac output, have a high risk of cardiogenic shock, or have significant AV block [7]. For patients with initial contraindications to early $\beta$-blocker therapy, once patients have hemodynamically stabilized, initiation of $\beta$-blockade should be considered. Additionally, a history of chronic obstructive lung disease or asthma is not a contraindication to the initiation of $\beta$-blockade in the absence of active airway disease [7].

**Calcium Channel Blockers**

Nondihydropyridine calcium channel blockers (i.e., diltiazem and verapamil) slow heart rate, lower blood pressure, decrease myocardial contractility, and provide mild coronary vasodilation. The Diltiazem Reinfarction Study, which involved 576 patients with non–Q-wave MI, showed that diltiazem reduced the rate of recurrent MI from 9.3% with placebo to 5.2% with diltiazem [157]. Similarly, the Danish Verapamil Infarction Trial (DAVID) II demonstrated a reduction of events, especially among patients without heart failure [158]. Not all trials, however, have shown a benefit with calcium channel blockade [159,160]. In fact, in patients with acute MI with significant LV dysfunction or heart failure, a harmful effect has been observed with the administration of diltiazem [161]. Short acting nifedipine (a dihydropyridine calcium channel blocker) has been shown to have harmful effects for patients with acute MI and is not recommended for patients with NSTE-ACS [162]. Thus, the current guidelines recommend that nondihydropyridine calcium channel blockers be used only for patients with preserved LV function and without heart failure, and then only if needed for recurrent ischemia despite the use of nitrates and $\beta$-blockade or for patients in whom $\beta$-blockade is contraindicated [7]. Calcium channel blockers should not be administered to patients at increased risk for cardiogenic shock or with significant AV block.

**Ranolazine**

Although the exact mechanism of its antianginal effects is unknown, ranolazine has been shown to partially inhibit fatty acid oxidation and may improve the efficiency of oxygen utilization in cardiac myocytes. In the Combination Assessment of Ranolazine in Stable Angina (CARISA) trial, researchers found that patients with stable angina who were treated with ranolazine in addition to $\beta$-blockers or calcium channel blockers had fewer episodes of angina (one episode less per week than placebo; $p < 0.02$) and showed increased exercise capacity (115.6 vs. 91.7 seconds; $p =$
Similar results reflecting the antianginal effects of ranolazine for patients with chronic stable angina were demonstrated by the MARISA (Monotherapy Assessment of Ranolazine in Stable Angina) trial [164]. The Metabolic Efficiency with Ranolazine for Less Ischemia in Non-ST Elevation Acute Coronary Syndrome (MERLIN)-TIMI 36 trial expanded the use of ranolazine to the NSTE-ACS population by evaluating 6,560 patients with NSTE-ACS, 3,279 of whom were randomized to receive ranolazine and 3,281 of whom received placebo. Although there was no difference of the primary end point (a composite of cardiovascular death, MI, or recurrent ischemia) between the two groups (21.8% vs. 23.5%; \( p = 0.11 \)), there was a significant reduction of the rates of recurrent ischemia with ranolazine (13.9% vs. 16.1%; \( p = 0.03 \)) [165]. Follow-up analyses of the MERLIN-TIMI 36 trial confirmed the results of the CARISA and MARISA trials and demonstrated that anginal symptoms were improved with ranolazine (HR 0.77; 95% CI 0.59 to 1.00; \( p = 0.048 \)) [166]. Hence, ranolazine remains an attractive addition to \( \beta \)-blockers and nitrates for treatment of chronic, severe angina.

**Angiotensin-Converting Enzyme Inhibitors**

Angiotensin-converting enzyme (ACE) inhibitors have been shown to reduce mortality for patients after MI, who have either LV systolic dysfunction (ejection fraction <40%) or heart failure [167,168]. A meta-analysis of nearly 100,000 patients demonstrated a statistically significant albeit small 0.48% absolute decrease (7% relative risk reduction) in 30-day mortality with the early initiation of ACE inhibitors following MI [169]. Benefit was seen as early as 24 hours; however, there was also an increase of hypotension and renal dysfunction seen with early initiation of ACE inhibition. These results suggest that ACE inhibitors may be safely initiated early following MI, but the benefits must be weighed against the risk for hypotension and renal dysfunction.

The long-term use of ACE inhibition has also been evaluated in a less acute setting for patients with a history of MI, peripheral arterial disease, or diabetes in the Heart Outcomes Prevention Evaluation trial [170]. Patients at increased risk of cardiovascular events without a history of heart failure or reduced LV systolic function randomized to ACE inhibition had a 22% reduction in ischemic events compared to placebo. Similar results were also seen in the European Trial on Reduction of Cardiac Events with Perindopril in Stable Coronary Artery Disease
(EUROPA) trial [171]. A third trial, however, the Prevention of Events with Angiotensin Converting Enzyme inhibition (PEACE) trial, did not show any benefit with the routine use of trandolapril for patients with stable coronary heart disease and preserved LV systolic function, possibly because this was a lower risk population treated with more aggressive baseline therapy [172]. The current guidelines recommend the use of ACE inhibitors for patients with NSTE-ACS with systolic dysfunction (LVEF < 40%), heart failure, hypertension, diabetes, or stable CKD [7].

Angiotensin Receptor Blockers

Angiotensin receptor blockers (ARBs) provide an alternative to ACE inhibitors, and may block the renin–angiotensin system more completely than ACE inhibitors, because angiotensin II can be generated via pathways that are independent of ACE [173]. The Valsartan in Acute Myocardial Infarction Trial (VALIANT) randomized nearly 15,000 patients with a recent MI complicated by heart failure to receive an ARB (valsartan), an ACE inhibitor (captopril), or a combination of the two drugs [174]. Valsartan was found to be noninferior to captopril at 2 years with regard to mortality ($p = 0.004$) and recurrent cardiovascular events ($p < 0.001$). VALIANT was subsequently followed by the On-going Telmisartan Alone and In Combination with Ramipril Global Endpoint Trial (ON-TARGET), which randomized patients with known vascular disease or diabetes to receive either telmisartan (an ARB), ramipril (an ACE inhibitor) or both drugs together [175]. Again, the ARB was shown to be noninferior to the ACE inhibitor with similar rates of death, MI, stroke, or hospitalization for heart failure at 56 months (16.5% vs. 16.7%; RR 1.01; 95% CI 0.94 to 1.09). Furthermore, patients who received telmisartan had less complaints of cough (1.1% vs. 4.2%; $p < 0.001$) when compared to those receiving the ACE inhibitor. Hence, ARBs are effective alternatives for patients who are intolerant of ACE inhibitors.

Mineralocorticoid Receptor Antagonism

Aldosterone blockade in addition to ACE inhibition lowers the rate of all-cause mortality of patients with severe heart failure and reduced systolic function [176]. The main adverse effect with aldosterone blockade is hyperkalemia. The Eplerenone Post–Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS) randomized 6,642 patients stabilized from a recent MI with LV dysfunction (LVEF <40%), plus heart failure or diabetes, to receive eplerenone (selective aldosterone blocker) vs. placebo in addition to optimal medical therapy [177]. At 24 months, eplerenone led to a 30% reduction in all-cause mortality. Aldosterone blockade is recommended for patients post-MI who are
receiving ACE inhibition, β-blockade, have an LVEF of ≤ 40%, and either heart failure or diabetes. It is not recommended for patients with renal dysfunction (men with creatinine >2.5 mg/dL or for woman with creatinine >2.0 mg/dL) or hyperkalemia (K⁺ > 5.0 meq/L) [7].

**Lipid-Lowering Therapy**

Long-term treatment with lipid-lowering therapy with statins has been shown to be beneficial in patients with a prior history of NSTE-ACS [178–180]. Furthermore, the Pravastatin or Atorvastatin Evaluation and Infection Therapy (PROVE-IT) TIMI 22 trial demonstrated the benefit of intensive lipid-lowering therapy with atorvastatin 80 mg compared to moderate lipid lowering therapy with pravastatin 40 mg in patients with a recent ACS [181]. Intensive lipid-lowering therapy resulted in a 16% reduction of the risk of recurrent ischemic events when compared with moderate lipid-lowering therapy. The benefits emerged after only 30 days post-ACS [182], highlighting the importance of early initiation of intensive statin therapy post-ACS. The average LDL-C achieved was 62 mg/dL for the atorvastatin 80 mg group and 95 mg/dL for the pravastatin 40 mg group. Based in part on these results, the adult treatment panel III of the National Cholesterol Education Program issued an update in which they recommended a new optional very low LDL-C goal of less than 70 mg/dL for patients with high-risk coronary heart disease [183]. More recently, the Improved Reduction of Outcomes: Vytorin Efficacy International Trial (IMPROVE-IT) evaluated the effects of ezetimibe plus simvastatin vs. simvastatin alone for stable patients with a recent ACS [184]. The addition of ezetimibe reduced LDL-C (54 mg/dL in the ezetimibe/simvastatin group vs. 70 mg/dL in the simvastatin monotherapy group). Over 7-year follow-up, there was a 6.4% relative risk reduction of recurrent ischemic events for the combination therapy group vs. the monotherapy group (Fig. 188.4). The relative risk reduction was consistent with what was expected based on the degree of LDL-C lowering [184,185]. The most recent AHA/ACC NSTE-ACS guidelines were published prior to completion of IMPROVE-IT; however, the current ESC NSTE-ACS guidelines recommend considering ezetimibe as adjunctive lipid-lowering therapy for patients with LDL ≥70 mg/dL despite a maximally tolerated statin [8]. A consensus statement from the ACC suggests a possible role for ezetimibe in addition to maximally tolerated statin for patients with a history of cardiovascular disease who are unable to achieve adequate LDL-C levels with a statin alone [186]. Similarly, the proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitor evolocumab was shown in the FOURIER trial to reduce major cardiovascular events when added to statin therapy in patients with a history of MI [201]. These
recommendations are supported by a meta-regression analysis demonstrating similar reductions of cardiovascular risk per degree of LDL-C lowering for therapies that lower LDL-C through modulation of the LDL receptor (i.e., statins, ezetimibe, bile acid sequestrants, and PCSK9 inhibitors) [185].

**FIGURE 188.4** Kaplan–Meier curves demonstrating the benefit of ezetimibe added simvastatin vs. simvastatin alone in reducing the 7-year event rates of the primary composite end point [death from cardiovascular disease, a major coronary event (nonfatal myocardial infarction, documented unstable angina requiring hospital admission, or coronary revascularization occurring at least 30 days after randomization), or nonfatal stroke] in patients with acute coronary syndrome (Adapted from The IMPROVE-IT Investigators: Ezetimibe Added to Statin Therapy after Acute Coronary Syndromes. N Engl J Med 372:21887–2397, 2015.).
TREATMENT STRATEGIES AND INTERVENTIONS

“Routine Invasive” vs. “Ischemia-Guided” Strategy of Coronary Angiography and Revascularization

Two general approaches to the use of coronary angiography and revascularization in NSTE-ACS exist. The first is a “routine invasive” strategy, involving routine coronary angiography within the first 72 hours and revascularization with PCI or bypass surgery as appropriate [7,8]. The other is a more conservative approach with initial medical management with coronary angiography and revascularization only for recurrent ischemia, which could be termed an “ischemia-guided” strategy. Several trials have compared these two treatment strategies; overall a routine invasive strategy lowers the risk of ischemic events compared with an ischemia-guided approach.

A seven trial meta-analysis demonstrated 25% lower rates of death and 17% lower rates of MI over 2-year follow-up with a routine invasive approach [187]. A subsequent meta-analysis including eight trials demonstrated similar findings with a 22% lower rate in the composite of death, MI, or rehospitalization for ACS over 1-year follow-up (Fig.188.5) [188]. The second meta-analysis demonstrated that whereas men overall seemed to benefit from a routine invasive approach, only high-risk women (identified by a positive cardiac biomarker) benefit from a routine invasive approach, and low-risk women (those without positive cardiac biomarkers) had a nonsignificant trend toward harm with a routine invasive approach. The current guidelines reflect these findings and recommend for a routine invasive approach for most patients except those who are low risk, notably low-risk women without an elevated troponin [7,8].
FIGURE 188.5 Meta-analysis of the benefit of a routine invasive vs. “selective” invasive (i.e., conservative) strategy for patients with unstable angina or NSTEMI. ACS, acute coronary syndrome. Rate of death or MI or rehospitalization with ACS through follow-up. [Adapted from O’Donoghue M, Boden WE, Braunwald E, et al: Early invasive vs conservative treatment strategies in women and men with unstable angina and non-ST-segment elevation myocardial infarction: a meta-analysis. JAMA 300(1):71–80, 2008.]

Timing of Invasive Strategy

Urgent Invasive

An urgent invasive strategy (ideally within 2 hours) is recommended for NSTE-ACS patients considered “very high risk” identified by one of the following clinical features: Angina refractory to medical therapy, hemodynamic instability, recurrent malignant arrhythmias, acute heart failure, or evidence of mechanical complications (Table 188.2) [7,8]. These recommendations are largely based on expert consensus, because patients with the above characteristics are traditionally excluded from randomized controlled trials [8].

### “Early” Invasive vs. “Delayed” Invasive

Routine invasive strategies have generally been defined as coronary angiography within 72 hours; however, a key question is whether patients benefit from an early invasive strategy (within the first 24 hours) vs. a delayed invasive strategy (24 to 72 hours). Two meta-analyses attempted to address this question and demonstrated no benefit for death or MI; however, both demonstrated lower rates of recurrent ischemia [189,190].

There is data suggesting improved outcomes with an early invasive
strategy for high-risk NSTE-ACS patients. The TIMACS trial randomized 3031 patients with NSTE-ACS to undergo an early invasive strategy (coronary angiography within 24 hours of randomization, median 14 hours) vs. a delayed invasive strategy (coronary angiography more than 36 hours after randomization, median 50 hours). Although the primary end point (composite of death, MI, or stroke) at 6 months was no different between the two groups, the prespecified analysis according to GRACE risk score demonstrated a significant 35% reduction of the primary end point for high-risk patients with a GRACE risk score >140 [96]. Accordingly the guidelines recommend that NSTE-ACS patients at high risk (i.e., GRACE score >140, or an elevated troponin compatible with MI) should undergo an early invasive strategy within the first 24 hours of presentation [7,8], whereas the remaining individuals should undergo coronary angiography within 72 hours of presentation.

High-Risk Subgroups

Elderly Patients

Age is a significant predictor of adverse outcomes among patients with NSTE-ACS [191]. Despite the increased risk, elderly NSTE-ACS patients are less likely to receive recommended evidenced based medical therapy or undergo an early invasive strategy [192]. Although some elderly patients may have contraindications to medications, registry data have shown lower mortality rates for patients on evidenced based medical therapy [193]. Similarly, an early invasive strategy for elderly NSTE-ACS patients has been associated with a lower risk of recurrent ischemic events from both registry and randomized controlled trial data [192,194]. The reduction in ischemic events, however, comes at the price of an increased risk of bleeding [194]. Therefore, in elderly patients with NSTE-ACS, the treatment strategy and use of evidence based medical therapy should be based on an individualized assessment, with careful consideration to weight and renal function when determining the optimal dose of medication.

Patients with Diabetes

In the setting of NSTE-ACS, patients with diabetes have worse outcomes compared to patients without diabetes. In a pooled analysis involving 15,459 NSTE-ACS patients, those with diabetes had an increased 30-day and 1-year mortality rate (2.1% and 7.2%, respectively) compared to those without diabetes (1.1% and 3.1%, respectively) [195]. Given the increased risk of adverse events, NSTE-ACS patients with diabetes should undergo a routine invasive strategy with coronary angiography within the first 72
In regard to antithrombotic therapy, patients with diabetes should be treated similarly to patients without diabetes. Both prasugrel and ticagrelor were associated with decreased ischemic events compared to clopidogrel in NSTE-ACS patients with diabetes [196,197]. Although outcomes in PLATO were similar regardless of diabetes status [195], in TRITON-TIMI 38, compared to patients without diabetes, patients with diabetes had a significantly greater net clinical benefit with prasugrel over clopidogrel [196].

**Patients with Chronic Kidney Disease**

NSTE-ACS patients with chronic kidney disease (CKD) have more comorbidities and a worse prognosis than those without CKD, yet they are less likely to receive evidence-based medical therapy or undergo routine coronary angiography [198,199]. Although there is limited data comparing a routine invasive vs. an ischemia-guided approach for patients with CKD, there is some evidence that a routine invasive approach may be preferred. A meta-analysis of 1,453 CKD patients from five randomized controlled trials comparing a routine invasive vs. an ischemia-guided strategy demonstrated a significant reduction of rehospitalization and trends toward decreased mortality and MI with a routine invasive approach [200].

These findings were supported by results from the Swedish Web-System for Enhancement and Development of Evidence-Based Care in Heart Disease Evaluated According to Recommended Therapies (SWEDEHEART) registry. Among 23,262 NSTEMI patients, the frequency of an invasive strategy decreased with worsening renal function. After adjustment for propensity score and discharge medications, an invasive strategy was associated with an overall 36% decrease of 1-year mortality throughout all patients with CKD. When the population was stratified according to CKD stage, the benefits seen with an invasive strategy were noted among patients with stage I though III CKD. For patients with stage IV CKD there was a trend toward benefit, but there was no benefit in stage V CKD [199]. In NSTE-ACS patients with stage I through III CKD, a routine invasive strategy is reasonable.

Evidence based pharmacotherapy for patients with CKD should be the same as for patients with normal renal function, although with dose modification or alternative therapies when appropriate based on degree of renal impairment.
CONCLUSIONS

Using the medical history, physical exam, ECG, and cardiac markers, clinicians can diagnose and risk-stratify patients with NSTE-ACS. These patients are treated with aspirin, a $P_2Y_{12}$ ADP receptor blocker (ticagrelor or prasugrel, or if cannot use either of those, then clopidogrel), an anticoagulant (UFH, LMWH, fondaparinux, or bivalirudin), and anti-ischemic therapy with nitrates and $\beta$-blockers. Risk stratification is used to properly match treatment strategy to patient risk (Fig. 188.6). For patients at intermediate to high risk, a routine invasive strategy is warranted. For patients at low risk, medical therapy is appropriate, and a more conservative ischemia-guided approach is reasonable.

Advances in NSTE-ACS, based on randomized controlled trials or meta-analyses of such trials, are summarized in Table 188.3.
• Identification of high-risk patients is key to management of NSTE-ACS [7,8]

• Aspirin leads to a significant reduction in the risk of death or MI [74,97–99]

• The addition of clopidogrel to aspirin further reduces risk by 20% [104]. Prasugrel and ticagrelor are alternative oral P2Y12 ADP receptor blockers that have been shown to be superior to clopidogrel for the reduction of ischemic events, at the expense of an increased risk of bleeding [111,114]. Cangrelor is a recently approved intravenous P2Y12 receptor blocker with a short onset and offset of action [8,106].

• Glycoprotein IIb/IIIa inhibitors can be considered in high-risk troponin-positive patients [130]; however, the benefit of upstream administration in patients undergoing urgent coronary angiography and percutaneous coronary intervention is questionable [131,132].

• Anticoagulation has been shown to be beneficial in treating patients with NSTE-ACS: Options include unfractionated heparin [136], low-molecular-weight heparin [138,139], fondaparinux [141], and bivalirudin [143].

• Early, intensive statin therapy is beneficial [181–183]

• The addition of ezetimibe and/or a PCSK9 inhibitor to statin therapy is beneficial [8,184,201]

• An early invasive strategy is beneficial in intermediate- and high-risk patients [187]

Patients admitted to the intensive care unit (ICU) are vulnerable to arrhythmias [1], which can cause hemodynamic compromise. The first priority is, therefore, to determine whether the patient has poor perfusion related to the dysrhythmia and whether emergent management is required [2]. In this situation, advanced cardiac life support (ACLS) should be promptly applied. Providers should always seek to reverse underlying processes (Table 189.1). The use of a pragmatic algorithm based on the electrocardiogram (ECG) can aid the diagnosis of arrhythmia; tachyarrhythmias and bradyarrhythmias are simply distinguished by a ventricular rate of >100 beats per minute (bpm) and <60 bpm, respectively. Tachyarrhythmias are broadly divided into wide complex tachycardias (WCTs) that have a QRS width >120 ms and narrow complex tachycardias, most of which are supraventricular tachycardias (SVTs). If the patient is sufficiently stable, providers may have time to perform a detailed assessment focusing on a relevant history, including ongoing symptoms, underlying cardiovascular disease, and medications, as well as pertinent laboratory tests. Continuous ECG monitoring should be implemented, and serial assessments are warranted because the patient can rapidly deteriorate at any time.

This chapter reviews commonly encountered arrhythmias among critically ill patients, including (I) ventricular arrhythmias (VAs), (II) supraventricular arrhythmias, and (III) bradyarrhythmias. A summary of an approach to common arrhythmias and their management is provided in Figures 189.1 through 189.5 and Table 189.2. Treatment of arrhythmias in patients with an existing implantable cardioverter defibrillator (ICD) or pacemaker is discussed in Chapters 15 and 18.

FIGURE 189.5 Approach to bradyarrhythmias (continue). Note that type I second-degree sinoatrial (SA) block with group beating and progressing shortening P-P interval before missing P and QRS complex. Figure presents 4:3 Mobitz I SA block. For AV block, type I second-degree AV block or Mobitz type I or Wenckebach-type block with progressive prolongation of the PR interval before failure of conduction of a P wave. Type II second-degree AV block or Mobitz type II with characteristics of constant P-P interval and pause duration of two times P-P intervals. This feature is distinguished from a premature atrial complex with physiologic block. Third-degree atrioventricular block or complete heart block with atrioventricular dissociation and ventricular escape rhythm.

**SECTION I: VENTRICULAR ARRHYTHMIAS**

Ventricular arrhythmias (VAs) are abnormal electrical signals arising...
below the level of the His bundle. VAs have a characteristic QRS width >120 ms and have clinical consequences that fall along a spectrum ranging from asymptomatic to cardiac arrest. VAs include ventricular fibrillation, polymorphic ventricular tachycardia, torsade de pointes, monomorphic-sustained ventricular tachycardia, premature ventricular complexes, nonsustained ventricular tachycardia, and accelerated idioventricular rhythm. Figure 189.1 summarizes the approach and common mechanisms of these arrhythmias.

**Ventricular Fibrillation (VF)**

VF is a disorganized rhythm that always causes inadequate cardiac output. VF or pulseless ventricular tachycardia (VT) accounts for 21% of in-hospital cardiac arrest. Approximately 40% of patients with in-hospital VF or pulseless VT survive hospitalization if prompt and effective ACLS is delivered [3].

The 2015 ACLS guidelines emphasize an integrated strategy of early defibrillation and effective chest compressions [4]. Witnessed cardiac arrest because of VF, pulseless VT, or TDP, should be treated with immediate defibrillation and effective cardiopulmonary resuscitation (CPR). Provision of uninterrupted pre- and postshock CPR is emphasized because it may take up to 200 seconds after a shock attempt until an organized rhythm returns [5]; uninterrupted CPR increases the likelihood of return of spontaneous circulation (ROSC) [6]. After two unsuccessful attempts of defibrillation, epinephrine can be used as a first-line vasopressor agent [4]. When VF or pulseless VT persists after three shocks, the administration of amiodarone is recommended [7]. Effort should be made to identify and correct the primary or precipitating causes. The management of cardiac arrest in special situations is summarized in Table 189.3 [8,9].

require aggressive fluid resuscitation with isotonic crystalloid. Epinephrine intravenous route may not be effective after 15 min of resuscitation, and vasopressin may be successfully used.

**Pregnancy**

ACLS consists of multidisciplinary care team. Continuous manual left uterine displacement is recommended during cardiac arrest. Providers should anticipate the difficult airway management, and no more than two attempts should be made for intubation. Perimortem cesarean delivery at the site of the arrest for patients with >20 wk of gestation is advisable if ROSC is not achieved with usual resuscitation.

**Pulmonary embolism**

In patients with confirmed PE, the guidelines provide a class IIa recommendation for considering thrombolysis, surgical embolectomy, and mechanical embolectomy during resuscitation.

**Hyperkalemia**

Severe hyperkalemia (>6.5 mmol/L) can cause a variety of abnormal rhythms, including VT, slow ventricular rate response, and sinus arrest. Stabilizing the myocardium with calcium chloride is the first-line treatment. Other treatment to shift potassium intracellularly (e.g., sodium bicarbonate) and promote potassium excretion should be followed in order of urgency.

**Hypokalemia**

No evidence to support intravenous bolus of potassium supplement during CPR. Replacement is generally achieved by infusion.

**Hypomagnesemia**

Especially in the setting of TDP, 1 to 2 g of MgSO₄ bolus is recommended. Administration of large, repeated doses of magnesium should be avoided in the presence of severe renal insufficiency because of its potential toxicity.

**Drug toxicity**

**Opioid**

Naloxone may be reasonable to use.

**Benzodiazepines**

The use of flumazenil, as an antidote, in patients with undifferentiated coma is not recommended because it may be associated with seizures, arrhythmias, and hypotension.

**β-Blockers**

Therapeutic antidotes include glucagon, insulin, and calcium. Antidotes with high-dose insulin and calcium have been described.

**Calcium channel blockers**

Cyclic antidepressants inhibit cardiac Na channel and cause widened QRS complex and VT. Many of these drugs also have a characteristic known as use-dependency, such that the administration of β-blockers can decrease their electrophysiologic effect. Administration of sodium bicarb
during cardiac arrest may be considered.

Digoxin

Antidigoxin Fab antibody should be administered to patients with severe life-threatening cardiac glycoside toxicity after resuscitation. Hyperkalemia is a marker of severity in acute cardiac glycoside poisoning and is associated with poor prognosis. Antidigoxin Fab may be administered empirically to patients with acute poisoning from digoxin whose serum potassium level >5.0 mEq/L.

Local anesthetic toxicity

Guidelines recommend considering intravenous long-chain fatty acid emulsion as an initial bolus during cardiac arrest, particularly in bupivacain toxicity.

Local anesthetic toxicity

Guidelines recommend considering intravenous long-chain fatty acid emulsion as an initial bolus during cardiac arrest, particularly in bupivacain toxicity.

Two small randomized controlled trials that enrolled patients with in-hospital cardiac arrest, including shockable VF/VT, suggested that combination of vasopressin-epinephrine and methylprednisone during early CPR cycles and subsequent stress-dose hydrocortisone for those who remained in shock were associated with an increase in ROSC and hospital survival [10,11]. Therefore, the 2015 guidelines recommend that this combined therapy may be considered (class IIb) for such cases [4]. After ROSC is achieved, lidocaine may be considered to reduce the risk of recurrence [4]. The guidelines recommend (class I) controlled temperature management between 32°C and 36°C for a patient with in-hospital arrest, irrespective of initial rhythms (shockable vs. nonshockable rhythms), who remains comatose after ROSC [4,12]. It is noteworthy that a prospective study of targeted temperature for patients with in-hospital cardiac arrest is not available.

**Polymorphic Ventricular Tachycardia (PMVT)**

PMVT is an unstable rhythm with a varying QRS morphology and axis from beat to beat. PMVT can look like VF and tends to degenerate into VF. Similar to VF, PMVT is commonly caused by acute myocardial ischemia, and, therefore, exclusion of an acute coronary syndrome is warranted [13]. Other less common causes include digoxin toxicity and catecholamine excess, for example, from inotropes commonly used in the ICU. The differential diagnosis of PMVT includes artifact (marked by normal QRS complexes visibly marching at the sinus rate through the artifact), atrial fibrillation (AF) with aberrancy, and preexcited AF (see “Section II: Supraventricular tachycardia” section). PMVT with an underlying prolonged QTc is called torsade de pointes (TDP).

Emergent defibrillation is warranted for all unstable patients with
PMVT. In hemodynamically stable patients, cardioversion, administration of intravenous magnesium, and lidocaine are initial steps. Antiarrhythmic drugs that can prolong QT interval (e.g., class IA and III agents, **Table 189.4**) should be avoided. For PMVT for which the baseline QTc interval is absolutely known to be normal, amiodarone can be administered. Use of atrioventricular nodal blockers for wide complex, irregular tachycardia of unclear etiology may precipitate VF and is contraindicated.

**Torsade de Pointes (TDP)**

TDP is a subtype of PMVT with an underlying prolonged QT interval during sinus rhythm and twisting of QRS complex around the isoelectric baseline during tachycardia (Fig. 189.1). TDP differs from PMVT in both underlying mechanism and treatment. TDP often has a characteristic onset with a slowing heart rate followed by a premature ventricular complex which interrupts the T wave, known as pause-dependent or a long–short ventricular cycle length. It is strongly related with QT-prolonging drugs, electrolyte abnormalities, or a congenital ion channel disorder. Hence, a meticulous search for these predisposing factors is critical (Table 189.1) [14]. Unlike VF or PMVT, TDP is generally not caused by acute myocardial ischemia.

Acute management for pulseless TDP includes emergent defibrillation. For unstable patients, synchronized cardioversion can be applied. As for hemodynamically stable patients, intravenous magnesium can be given for the purpose of treatment and prevention, irrespective of serum magnesium level. If baseline rhythm is bradycardia, atrial pacing at a rate of at least 90 bpm or isoproterenol administration may suppress the TDP [15].

**Monomorphous Ventricular Tachycardias (VT)**

VT is defined as three or more consecutive ventricular beats at a rate greater than 100 bpm. Sustained VT is defined as VT causing hemodynamic compromise or VT that lasts more than 30 seconds. Different from PMVT, monomorphous VT has uniform QRS morphology. VT is the most common cause of wide complex tachycardia (WCT) encountered in clinical practice [16]. Therefore, WCT should be managed as VT until proven otherwise [17]. Lack of significant symptoms should
not exclude the diagnosis of VT; minimal symptoms may occur for a patient without underlying cardiopulmonary disease and relatively slow VT.

Differential diagnosis of WCT includes SVT with rate-related aberrant interventricular conduction, SVT with abnormal baseline QRS configuration or ventricular pacing rhythms, and SVT with nonspecific wide QRS complexes because of medications or electrolyte abnormalities [2]. SVT with antegrade conduction over an accessory pathway or preexcitation syndrome is a less common cause of WCT and is discussed in “Section II: Supraventricular tachycardia” section.

Characteristic ECG for the Diagnosis of Ventricular Tachycardia

Careful evaluation of 12-lead ECGs often provides the distinction between VT and SVT (Fig. 189.6). It is necessary to integrate several ECG features for the diagnosis of VT because there is no perfect single criterion. In unstable patients, relatively simple criteria using the QRS axis, the presence of AV dissociation and concordance on the precordial leads can be used to differentiate VT. It is important to note that among patients with known structural heart disease, VT is the most likely cause of WCT.

**FIGURE 189.6** Monomorphic ventricular tachycardia (VT). Figure A demonstrates regular wide complex tachycardia with northwest axis and atypical RBBB pattern (single R wave in V1, and prominent S wave in V6). Atrioventricular dissociation, fusion beat (*, Fig. B), and positive concordance of QRS complexes.

Courtesy of Thomas M. Munger, MD and Stephen C.
Regularity—VT is generally regular; irregular WCT is most commonly as a result of AF ([Fig. 189.1](#)).

AV relationship—AV dissociation or ventricular rhythm faster than an independent atrial rhythm is the hallmark of VT. AV dissociation can be suggested by the presence of fusion (QRS morphology with mixed features between a normal beat and a ventricular beat [Fig. 189.6](#)) and captured complexes (QRS complex identical to one seen in sinus rhythm but that occurs in the midst of WCT). Related to AV dissociation, examination may reveal irregular cannon A waves in the jugular venous pulses resulting from periodic atrial contraction dissociated with tricuspid valve closure.

QRS axis—WCT with axis of −60° to −120°, particular that WCT falling in the northwest axis (−90° to −180°) and the axis that shifts from the baseline >40° are suggestive of VT [8].

Precordial leads—if QRS polarities of the precordial leads are all negative or positive from V1 through V6 (i.e., concordance), WCT is likely VT.

Right bundle branch block (RBBB) and left bundle branch block (LBBB) patterns—Generally, any patterns of atypical RBBB or atypical LBBB are considered VT ([Table 189.5](#)).

Brugada criteria—including four stepwise approaches, these criteria are the most widely known algorithm for identifying VT ([Fig. 189.7](#)) [18]. Its diagnostic performance varies among clinicians with the sensitivity >79% and specificity ~60% [17,19].

Pathophysiology and Etiology

Different from VF, PMVT and TDP, the most common mechanism of monomorphic VT is underlying myocardial scarring, as a substrate for reentry, in patients with a prior infarction or cardiomyopathy. Precipitating factors should be considered and excluded; such triggers commonly encountered in the ICU include a hyperdynamic state and intracardiac catheters. All antiarrhythmic drugs can be proarrhythmic, and the decision whether to continue or discontinue therapy should be discussed with a cardiologist. If available, a serum drug level (e.g., amiodarone, digoxin, quinidine, procainamide) may be obtained. Digoxin toxicity can cause a variety of arrhythmias, including AV block, tachyarrhythmias, and bidirectional VT which is characteristic but rare. Tricyclic antidepressants and other sodium channel blocking drugs (e.g., flecainide, propafenone, quinidine, procainamide,
disopyramide, phenothiazines) can slow ventricular conduction (reflected by a widened QRS complex), and cause very rapid VT known as ventricular flutter [20,21].

Initiation of the ACLS algorithm and defibrillation is warranted for pulseless VT [4]. Unstable patients with palpable pulses require immediate cardioversion with appropriate sedation and analgesia. Medical therapy can be administrated in hemodynamically stable patients. Antiarrhythmic drugs in a patient with unknown etiology of VT include class I (procainamide or lidocaine) or class III antiarrhythmic drugs (amiodarone or sotalol). Amiodarone has superior efficacy for terminating most VA and rarely has an absolute contraindication in the acute setting [15]. Preference of each drug’s profile and possible side effects are summarized in Table 189.4. Synchronized cardioversion can be used for persistent VT. Maintenance antiarrhythmic therapy may be required to prevent acute recurrence, and a cardiology consult is recommended for all patients with VT. Vagal maneuvers or adenosine administration may be attempted in the rare circumstance of very high suspicion for SVT in hemodynamically stable patients with a regular WCT. These maneuvers inhibit the AV node and often terminate SVT but have little effect on VT. Vagal maneuvers or adenosine administration are contraindicated for PMVT suspicious for AF with preexcitation.

**Ventricular Tachycardia Storm**

VT storm is defined as an occurrence of ≥3 episodes of sustained VT/VF within 24 hours. VT storm is a true emergency and requires a multidisciplinary approach. VT storm is commonly associated with a hyperadrenergic state, and treatment with $\beta$-blockers has been shown to improve mortality [22]. Choices include intravenous metoprolol or esmolol which has a shorter half-life and is attractive for patients with severe hemodynamic compromise. In addition, amiodarone should be administered during the acute phase even if the patient is already receiving an oral formulation [15,23]. Amiodarone is recommended over lidocaine owing to its superior effectiveness for treatment of most VAs. Treatment of reversible causes is always critical. Additionally, medical optimization of heart failure is necessary because electrical instability can be a manifestation of pump failure [24].

If medical therapy is not successful, sedation and intubation may significantly suppress electrical storm. Neuraxial modulation for suppression of hyperdynamic state may also be warranted [25]. Mechanical circulatory support may facilitate suppression of VT storm in patients for whom ischemia or hemodynamic stress are driving triggers. Thoracic epidural anesthesia with intrathecal clonidine or bupivacaine at bedside can reduce the arrhythmic burden [24,25]. Further, sympathetic
denervation and stellate ganglionectomy by a video-assisted thoracoscopic approach may be considered for refractory cases [24].

Non-Sustained Ventricular Tachycardia

NSVT is relatively common and generally not associated with symptoms. Little is known about the prognostic implications of NSVT in a structurally normal heart or nonischemic cardiomyopathy. NSVT, however, is associated with a higher risk of sudden cardiac death among patients with a history of myocardial infarction. Polymorphic NSVT should prompt a thorough evaluation for acute ischemia. General management focuses on correction of triggers and identifying underlying structural heart disease, which will dictate subacute and long-term management. A primary prevention ICD may be considered for postinfarct patients with left ventricular ejection fraction <40% and a positive electrophysiology study [26].

Premature Ventricular Contraction

Premature ventricular contractions (PVCs) are ectopic ventricular contractions with wide QRS complex occurring for <3 consecutive beats. PVCs are very common and can be found in a healthy population [15]. In rare circumstances, PVCs may be associated with poor outcomes; for example, in patients with severely depressed ventricular function or dyssynchronization, PVCs can precipitate heart failure. Very frequent PVCs >10,000 to 20,000 beats per 24 hours, or >20% of all beats, may cause PVC induced cardiomyopathy. Management focuses on identifying any underlying structural heart disease and correctable triggers. In patients without structural heart disease, specific medical therapy for PVCs is rarely warranted.

Accelerated Idiopathic Ventricular Rhythm

Accelerated idiopathic ventricular rhythm (AIVR) is a wide complex ventricular rhythm at a lower rate of VT (i.e., 40 to 100 bpm). This rhythm often occurs during the first 12 hours following reperfusion of an acute myocardial infarction during periods of elevated sympathetic tone. AIVR usually resolves without specific therapy. Electrolyte abnormalities (e.g., hyperkalemia) and ventricular pacing rhythm can mimic AIVR.

Subacute and Long-Term Management

Subacute and long-term management of VAs requires an assessment for the underlying structural cardiac disease [15]. After cardiac arrest, ventricular function may initially be depressed because of myocardial
stunning, and, therefore, repeat imaging is required during follow-up. VF and PMVT are most commonly caused by acute coronary ischemia, and prompt revascularization can significantly improve prognosis even in cases without ST elevation myocardial infarction [13]. While TDP and monomorphic VT are not generally related to ischemia, other treatable triggers commonly observed in the ICU should be evaluated (Table 189.1).

The choice and duration to maintain antiarrhythmic drugs should be directed by a multispecialty team. Reassessment of ventricular function 40 days after myocardial infarction or 90 days after revascularization will determine the need for ICD implantation. However, in patients with persistent VAs, ICD implantation is indicated prior to dismissal. Postmyocardial infarction patients with impaired left ventricular ejection fraction are at a higher risk of sudden cardiac death in the first 3 months. Although not yet adequately studied by adequately powered randomized trials, such patients may benefit from a wearable defibrillator upon hospital discharge.

Long-term management following an episode of VAs is largely dictated by the residual risk and the underlying structural heart disease. Among patients with cardiomyopathy, β-blockers and an angiotensin-converting enzyme inhibitor are associated with a significant reduction in risk of sudden cardiac death [27–29].

Arrhythmias in Stress-Induced Cardiomyopathy

Reversible cardiomyopathy as a result of acute severe illness known as stress-induced cardiomyopathy or apical ballooning syndrome or takotsubo cardiomyopathy, can be found in approximately 28% of critically ill patients [18]. It is associated with remarkable ECG changes that are relatively similar to acute myocardial ischemia. Therefore, stress-induced cardiomyopathy is a diagnosis of exclusion. Gigantic T wave inversion and prominent QT prolongation are frequently evident with peak prolongation occurring 2 to 3 days postadmission (Fig. 189.8). Arrhythmias are common in this setting, with reported frequencies of 4.7% for AF, 2.2% sustained VT, and 1.2% VF. Risk of VAs appears to be highest at the peak of longest QT interval and maximal T wave inversion [30]. Therefore, patients should be monitored during this critical period.
Given that catecholamine surge during critical illness is likely a culprit of stress-induced cardiomyopathy, early administration of a $\beta$-blocker is a mainstay of treatment. However, $\beta$-blockers for patients with bradycardia or severe QTc prolongation should be prescribed cautiously because TDP could be related to pause or bradycardia. Noteworthy, an increase in the awareness of genetic syndromes predisposing patients with stress-induced cardiomyopathy to have markedly prolonged QT interval has been recognized. Thus, a careful personal and family history should be collected, and referral to an electrophysiologist should be considered [30].
SECTION II: SUPRAVENTRICULAR TACHYCARDIA

SVTs are among the most commonly encountered arrhythmias in the ICU setting, and can cause considerable morbidity and mortality for critically ill patients. A structured approach to facilitate prompt diagnosis and management of these rhythms is displayed in Figures 189.2 and 189.3.

The 2015 American College of Cardiology/American Heart Association and the Heart Rhythm Society (ACC/AHA/HRS) guidelines for the management of the adult patients with SVT define SVT as a tachycardia originating above the level of the His bundle [31]. A ventricular rate that exceeds 100 bpm and a narrow QRS complex (QRS width < 120 ms) are the hallmarks of SVT. Less commonly, a WCT can be owing to SVT with bundle branch block or aberrant conduction. Differentiation of SVT from VT using the 12-lead ECG is discussed in Section I.

SVTs are classified as regular narrow complex tachycardias, characterized by regular intervals between successive R waves or as irregular narrow complex tachycardias, with irregular R-R intervals. The differential diagnosis of regular narrow complex tachycardia includes sinus tachycardia, atrioventricular nodal reentrant tachycardia (AVNRT), atrioventricular reentrant tachycardia (AVRT), and focal atrial tachycardia. Irregular narrow complex tachycardias include AF and multifocal atrial tachycardia (MAT). Atrial flutter (AFL) can present as a regular narrow complex tachycardia, but can be irregular owing to variable AV conduction block. Furthermore, the management approach to AF and AFL is very similar, and, hence, AFL is discussed in “Irregular Narrow Complex Tachycardia” section.

Regular Narrow Complex Tachycardia

Ventricular response greater than 100 bpm, QRS width <120 ms, and regular R-R intervals define regular narrow complex tachycardia. Sinus tachycardia, AVNRT, AVRT, focal atrial tachycardia, and AFL are the most important considerations for the differential diagnosis of these rhythms (Fig. 189.9). Particular attention to three key electrocardiographic features will allow differentiation of regular narrow complex tachycardias. First, the onset and termination of tachycardia can be sudden (AVNRT and AVRT) or gradual (sinus tachycardia). Atrial tachycardia can present in either fashion (Figs. 189.2 and 189.3). Second, the ECG should be scrutinized for the presence and timing of P waves. If the P wave occurs closer to the preceding QRS complex (short R-P
tachycardia), AVNRT and AVRT are more likely, although important exceptions exist (Fig. 189.2) [32]. If the P wave occurs closer to the succeeding QRS complex (long R-P tachycardia), sinus tachycardia and atrial tachycardia are more likely. Finally, the morphology of the P wave can differentiate sinus tachycardia from atrial tachycardia. Sinus P waves are upright in leads II, III, and aVF and biphasic in lead V1. An abrupt change in P wave morphology should alert the clinician to an atrial tachycardia [32–34].

**FIGURE 189.9** Genesis of commonly encountered regular narrow complex tachycardia.

**Sinus Tachycardia**

Sinus tachycardia is a commonly encountered rhythm in the ICU setting. It is usually a normal physiologic response to a hyperadrenergic state caused by shock, pain, systemic inflammation, adrenergic medications, or rarely endocrine disturbances such as hyperthyroidism. It is characterized by a ventricular rate greater than 100 bpm, sinus P wave morphology, long R-P interval, and gradual onset and offset. Sinus tachycardia will resolve with treatment of the underlying cause.

Occasionally, sinus tachycardia can result in cardiac ischemia in patients with severe coronary artery disease. Other conditions where maximizing the diastolic interval is important are severe mitral stenosis and restrictive cardiac physiology as seen in heart failure with preserved ejection fraction. In these situations, temporary use of short-acting β-blockers or calcium channel blockers to reduce the sinus rate is warranted.

**Focal Atrial Tachycardia**
Focal atrial tachycardias are regular narrow complex, long R-P interval SVTs that arise from regions other than the sinus node. The mechanism can be automatic, triggered activity, or reentry. The morphology of the P waves can help differentiate focal atrial tachycardias from sinus tachycardia. Atrial tachycardias can have sudden onset, especially if a reentrant mechanism is involved.

In contrast to sinus tachycardia, the fast heart rates with focal atrial tachycardia are usually inappropriate, and treatment with β-blockers or calcium channel blockers is reasonable in acute situations if the increased heart rate is poorly tolerated [31]. Vagal maneuvers and adenosine can slow the ventricular response and allow for diagnosis of the atrial rhythm, and can terminate atrial tachycardia owing to triggered activity [35]. Second-line options for termination include intravenous class IC agents such as flecainide [36] and intravenous class III agents such as ibutilide and amiodarone (Table 189.4) [37,38]. Overdrive pacing through an existing atrial lead can terminate the tachycardia, and should only be performed under expert guidance [31].

Atrioventricular Nodal Reentrant Tachycardia

AVNRT is often categorized as a paroxysmal SVT, because of abrupt onset and offset. It is the most common regular SVT, and is more common in women than in men [39]. There is usually a history of previous episodes beginning in second or third decade of life. The ventricular rate is often between 150 and 250 bpm, but can occasionally exceed 250 bpm [40].

Impulses from the sinus node are conducted to the AV node via the “fast” pathway and the “slow” pathway. The fast pathway is typically anatomically located anteriorly in the right atrium and conducts impulses rapidly to the AV node. The slow pathway is anatomically located posteriorly along the ostium of the coronary sinus. During normal conduction, impulses travel down the fast pathway to the Atrioventricular node (AV node), resulting in ventricular conduction. There is retrograde activation of the slow pathway, and, as a result, the antegrade activation of the slow pathway does not reach the AV node. Differences in the refractory periods of the two pathways can result in initiation and maintenance of AVNRT [41,42]. When a premature atrial contraction (PAC) occurs, the fast pathway can be refractory from the previous sinus beat, and the wavefront travels down the slow pathway. If the PAC is timed critically, the fast pathway may have recovered by the time the wavefront reaches the AV node, resulting in retrograde conduction up the fast pathway, establishing a reentrant circuit. This is the underlying pathophysiology of “typical” AVNRT, which occurs in about 80% cases.

The surface ECG shows a PAC with prolonged PR interval (owing to conduction down the slow pathway), followed by a sudden onset regular
narrow complex tachycardia. Retrograde P waves can be seen after each QRS complex, and, hence, this tachycardia has a short R-P interval (Fig. 189.10). Although this tachycardia is usually well tolerated, older patients and critically ill young patients may not tolerate it well.

AVNRT usually responds well to vagal maneuvers which is the first-line therapy in acute management (Fig. 189.2) [43,44]. The Valsalva maneuver can be performed easily at the bedside and can terminate AVNRT. Other maneuvers, such as carotid massage (after exclusion of a bruit), applying an ice cold towel to the face, can also be effective. Eyeball pressure is no longer recommended as a vagal maneuver owing to the potential for harm [31]. If these fail, intravenous adenosine is almost always successful in terminating AVNRT [45,46]. It can also help unmask a cause for SVT other than AVNRT by slowing the ventricular response and allowing the diagnosis of unrecognized atrial tachycardia or flutter. Intravenous β-blockers and calcium channel blockers are rarely required for treatment [47]. If patients have recurrent AVNRT in the ICU, oral therapy with calcium channel blockers or β-blockers can be effective in preventing recurrences [48]. Catheter ablation is widely utilized in the outpatient setting for definite management of AVNRT, but very rarely performed during an acute illness [49].

Atrioventricular Reentrant Tachycardia

Accessory pathways are myocardial fibers that connect atrial myocardium directly to ventricular myocardium [31]. The presence of an accessory
pathway can permit conduction of impulses directly from the atrium to the ventricle (anterograde conduction or antidromic AVRT) or conduction of impulses from the ventricle to the atrium (retrograde conduction or orthodromic AVRT). In sinus rhythm, the surface ECG may reveal short PR interval, a “delta wave” and some degree of fusion between impulses conducted down the accessory pathway and the AV node (Fig. 189.11).

![Short PR interval and delta wave](image)

**FIGURE 189.11** An electrocardiogram demonstrates short PR interval and “delta wave” in sinus rhythm.

Presence of an accessory pathway can result in three clinical presentations relevant to intensive care physicians. First, a PAC can conduct down the AV node and up the accessory pathway, resulting in a reentrant tachycardia (orthodromic AVRT). The ECG will show a regular narrow complex tachycardia with a short R-P interval, similar to AVNRT. This is the most common tachycardia in patients with accessory pathways. Second, there can be a reentrant tachycardia with conduction down the accessory pathway and up AV node (antidromic AVRT: Fig. 189.12). Antidromic AVRT is a regular tachycardia with a wide complex QRS on the surface ECG, because conduction is directly to the ventricular tissue and not through the usual conduction system.
Finally, an atrial arrhythmia such as AF or AFL can conduct down the accessory pathway, resulting in extremely rapid heart rate (preexcited AF/AFL: Fig. 189.13). The difference between preexcited AF and antidromic AVRT is that the AV node is not involved in the tachycardia circuit. Presence of preexcitation on the surface ECG and an associated SVT is diagnostic for Wolff–Parkinson–White ( WPW) syndrome. Preexcited AF is commonly associated hemodynamic instability and is best treated with cardioversion in unstable patients [31]. VF can occur among patients with preexcited AF. If patients are hemodynamically stable, intravenous procainamide [50] or ibutilide [51] can be administered (Table 189.4). The use of any AV nodal blocking agents is contraindicated in preexcited AF, because these agents increase conduction down the accessory pathway and can precipitate VF.
It is uncommon for orthodromic or antidromic AVRT to cause hemodynamic instability, because the circuit involves the AV node, which has decremental conduction properties. Nevertheless, hemodynamically unstable patients with either of these rhythms should undergo cardioversion. In hemodynamically stable patients, the management is similar to AVNRT. Vagal maneuvers should be attempted first [52] followed by intravenous adenosine [53]. Intravenous β-blockers or calcium channel blockers can also terminate the tachycardia. Catheter ablation of the accessory pathway is the definitive treatment and is usually performed in the outpatient setting.

Irregular Narrow Complex Tachycardia

When evaluating an irregular narrow complex tachycardia, AF, AFL with variable block, and MAT should be considered. Among these, AF is the most common, and is actually the most common arrhythmia worldwide [54].

Atrial Fibrillation (AF)

AF is present in about 1% of the general population and in 9% of adults older than 80 years [55]. AF occurs as the result of chaotic and uncoordinated atrial activation and is characterized by the absence of P waves and irregular R-R intervals on the surface ECG (Fig. 189.3).
Morbidity from AF is a consequence of rapid ventricular rates, lack of atrial contraction, and the propensity for clot formation in the left atrium with consequent risk of systemic embolization. AF is classified as valvular or nonvalvular according to the presence or the absence of significant mitral stenosis or prosthetic valve. It is also classified based on duration of AF as paroxysmal (terminates spontaneously or within 7 days of onset), persistent (AF for >7 days), long-standing persistent (AF > 12 months), or permanent (persistent AF with no further attempts at restoration of sinus rhythm) [56].

Among ICU patients, AF can result in hemodynamic instability because of rapid ventricular rates. This is especially true for cases with restrictive left ventricular filling, such as diastolic dysfunction, hypertrophic cardiomyopathy, or restrictive cardiomyopathy. AF can cause instability for any patient in whom a longer diastolic filling period is desirable, such as patients with severe mitral stenosis, constrictive pericarditis, or severe coronary artery disease. As discussed previously, patients with WPW syndrome can experience severe hemodynamic instability and even VF if they develop AF and antegrade conduction down the accessory pathway.

Etiology and Pathophysiology

AF can be considered a final common manifestation of several processes that favor increased ectopy and reentry in the left atrial myocardium. The interplay of rapidly discharging foci, usually of the pulmonary veins, atrial substrate abnormalities that favor reentry, and autonomic disturbances that trigger atrial activation results in initiation and maintenance of AF [57].

There are several well-recognized risk factors that contribute to these aforementioned processes. Apart from increasing age, hypertension is the most prevalent risk factor for AF. Congestive heart failure arising from ischemic heart disease, dilated cardiomyopathy, myocarditis, valvular heart disease, or congenital heart disease is a common and important risk factors for AF. Ischemia itself can precipitate AF, without an accompanying cardiomyopathy. In addition to the classic risk factors, obesity and metabolic syndrome, obstructive sleep apnea, hyperthyroidism, chronic kidney disease, and any process resulting in systemic inflammation can contribute to AF [58–60]. It is important to recognize pulmonary embolism as a trigger for AF. Excessive alcohol consumption (holiday heart syndrome), toxicities from drugs of abuse such as cocaine, and medications such as inotropes can result in AF [61,62].

A special mention must be made of AF in the postoperative period. Increased sympathetic tone in postoperative states as a result of inflammation, fluid shifts, and pain contribute to increased incidence of
AF. Cardiac surgery patients are particularly at risk of developing AF, and up to 40% of postcardiac surgery patients can develop AF [63]. Postoperative amiodarone and β-blockers can decrease the incidence of AF in this group of patients [64,65]. The genesis of AF among cardiac surgery patients is multifactorial, and atrial incisions, pericardial inflammation, and atrial ischemia are all thought to contribute.

The electrophysiologic basis for AF requires a trigger for initiation and substrate for maintenance. Triggers for AF include rapid discharges from the myocardial sleeves that surround pulmonary veins, electrolyte abnormalities causing increased atrial ectopy, and abnormal intracellular calcium handling, resulting in triggered after depolarization [66]. Conditions favoring reentry form the substrate for maintenance of AF. The haphazard orientation of pulmonary venous myocytes, atrial fibrosis from atrial dilation, and scar tissue formation from ischemia or previous surgery are all foci of reentry and favor maintenance of AF. In addition, AF itself results in structural and electrical remodeling, and, hence, the tenet “AF begets AF [67].”

Management

The ultimate clinical goals of AF treatment include amelioration of symptoms, including palpitations, fatigue, dyspnea, lightheadedness, prevention and treatment of heart failure including tachycardia-induced cardiomyopathy, and prevention of stroke. These goals are usually achieved through either adequate control of the ventricular rate or restoration of sinus rhythm.

AF is associated with increased mortality after adjustment of confounders. However, in the outpatient setting, it is unclear whether long-term treatment of AF improves outcomes [68]. Among ICU patients, AF can result in hemodynamic instability or ischemia or both. For the hemodynamically unstable patient, synchronized direct cardioversion is indicated. A careful search must be made for precipitating factors for all patients once stabilized. Any condition causing sympathetic activation can precipitate AF. Common ICU-associated causes include sepsis, myocardial ischemia, pulmonary embolism, systemic inflammation, pericarditis, and stroke (Table 189.1). Addressing and treating these conditions can result in spontaneous resolution of new-onset AF. Administration of sympathomimetic agents is common in ICU settings and can cause AF. Electrolytes must be checked, and hypokalemia and hypomagnesemia in particular must be corrected.

Apart from controlling these precipitants of AF, a rate control or rhythm control approach may be pursued for management [56]. Rate control refers to a strategy of using drugs that increase the refractoriness of the AV node to impulse propagation, resulting in a controlled
ventricular rate. Oral or intravenous β-blockers, calcium channel blockers, digoxin, and even amiodarone can be used for rate control. Rhythm control is a strategy of converting AF into sinus rhythm and can be achieved by electrical synchronized cardioversion or pharmacologic cardioversion with medications. From a standpoint of long-term management, a large multicenter randomized controlled trial found no difference in endpoints when rhythm control was compared with rate control [69]. In the ICU setting, because of high rates of recurrent AF, rate control is the most commonly adopted management strategy for AF; rhythm control is reserved for AF that is difficult to rate control.

**Prevention of Thromboembolic Complications**

The association of stroke and AF is well described. Stasis of blood in the left atrial appendage, a hypercoagulable state induced by AF itself result in left atrial thrombosis and systemic embolization. Risk factors for stroke among patients with AF are easily recalled by the CHA2DS2VASc scoring system recommended be the ACC/AHA/HRS 2014 AF guidelines [56]. Increasing scores are indicative of increasing annual incidence of stroke, 6.7% per year in patients with a score of 9 [70]. Anticoagulation can be avoided for patients with a score of 0, and anticoagulants are indicated for patients with a score of ≥2. A score of 2 represents a gray area, and no therapy, aspirin alone, or anticoagulation can be considered for management based on patient preference and the clinical scenario. Stroke prevention with anticoagulation is counterbalanced by the risk of intracranial and extracranial bleeding with anticoagulation [56]. While warfarin was the mainstay of anticoagulation for AF in the past, novel oral anticoagulants, including dabigatran, rivaroxaban, apixaban, and edoxaban, are now commonly utilized for thromboprophylaxis.
